ABSTRACT

Serological detection of antibodies to SARS-CoV-2 is essential for establishing rates of seroconversion in populations, detection of seroconversion after vaccination, and for seeking evidence for a level of antibody that may be protective against COVID-19 disease. Several high-performance commercial tests have been described, but these require centralised laboratory facilities that are comparatively expensive, and therefore not available universally. Red cell agglutination tests have a long history in blood typing, and general serology through linkage of reporter molecules to the red cell surface. They do not require special equipment, are read by eye, have short development times, low cost and can be applied as a Point of Care Test (POCT). We describe a red cell agglutination test for the detection of antibodies to the SARS-CoV-2 receptor binding domain (RBD). We show that the Haemagglutination Test ("HAT") has a sensitivity of 90% and specificity of 99% for detection of antibodies after a PCR diagnosed infection. The HAT can be titrated, detects rising titres in the first five days of hospital admission, correlates well with a commercial test that detects antibodies to the RBD, and can be applied as a point of care test. The developing reagent is composed of a previously described nanobody to a conserved glycophorin A epitope on red cells, linked to the RBD from SARS-CoV-2. It can be lyophilised for ease of shipping. We have scaled up production of this reagent to one gram, which is sufficient for ten million tests, at a cost of ~0.27 UK pence per test well. Aliquots of this reagent are ready to be supplied to qualified groups anywhere in the world that need to detect antibodies to SARS-CoV-2, but do not have the facilities for high throughput commercial tests.

INTRODUCTION

Red cell agglutination tests have a distinguished history. Since Landsteiner's classic observations in 1901 (Landsteiner, 1961) (English translation), they have been used for the

95 determination of blood groups (Schwarz & Dorner, 2003) detection of influenza viruses (Hirst,
96 1941) and in a wide variety of applications championed by Prof. Robin Coombs for the
97 detection of specific antibodies or antigens (Coombs, Mourant, & Race, 1945) (reviewed by
98 (Pamphilon & Scott, 2007)). They have the great advantage of being simple, inexpensive, can
99 be read by eye, and do not require sophisticated technology for their application. In the
100 recent era the linkage of an antigen to the red cell surface has become easier with the
101 possibility of fusing a protein antigen sequence with that of a single domain antibody or
102 nanobody specific for a molecule on the red cell surface (discussed in (Habib et al., 2013)).
103
104 We have applied this concept to provide a simple Haemagglutination Test ("HAT") for the
105 detection of antibodies to the Receptor Binding Domain (RBD) of the SARS-CoV-2 spike
106 protein. The RBD is a motile subdomain at the tip of the SARS-CoV-2 spike protein that is
107 responsible for binding the virus to its ACE2 receptor. The RBD of betacoronaviruses folds
108 independently of the rest of the spike protein (Lan et al., 2020; Li, Li, Farzan, & Harrison, 2005;
109 Wang et al., 2020; Yan et al., 2020). This useful property provides an Achilles' heel for the
110 virus and allows many potential applications in vaccine design (Dai et al., 2020; Mulligan et
111 al., 2020; Tan et al., 2020; Walls et al., 2020; Yang et al., 2020; Zha et al., 2020), and serology
112 (Amanat et al., 2020; Piccoli et al., 2020; The National SARS-CoV-2 Serology Assay Evaluation
113 Group, 2020), see also www.gov.uk/government/publications/COVID-19-laboratory-
114 evaluations-of-serological-assays). The majority of neutralising antibodies bind to the RBD
115 (Barnes et al., 2020; Piccoli et al., 2020), and the level of antibody to the RBD detected in
116 ELISA correlates with that of neutralising antibodies (Amanat et al., 2020; Piccoli et al., 2020;
117 Robbiani et al., 2020). We reasoned therefore that a widely applicable and inexpensive test
118 for antibodies to the RBD would be useful for research in settings where high throughput
119 assays were not available.
120
121 In order to link the SARS-CoV-2 RBD to red cells we selected the single domain antibody
122 (nanobody) IH4 (Habib et al., 2013), specific for a conserved epitope on glycophorin A.
123 Glycophorin A is expressed at up to 10^6 copies per red cell. The IH4 nanobody has previously
124 been linked to HIV p24 to provide a monomeric reagent that bound p24 to the red cell surface.
125 Antibodies to p24 present in serum cross-linked the p24 and agglutinated the red cells (Habib
126 et al., 2013). We have adapted this approach to detection of antibodies to SARS-CoV-2 by

127 linking the RBD of the SARS-CoV-2 spike protein to IH4 via a short (GSG)2 linker to produce
128 the fusion protein IH4-RBD-6H (Figure 1).

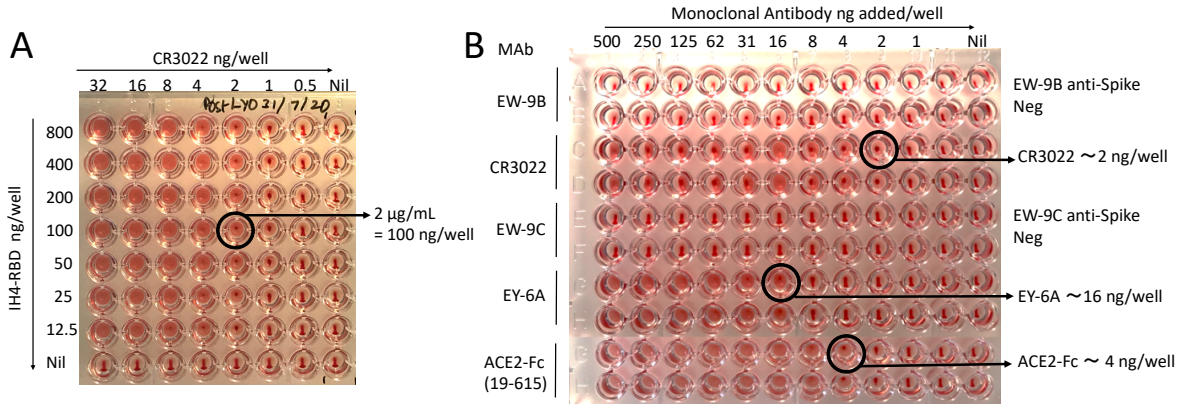
135 B) Sequence of VHH(IH4)-RBD fusion protein. Residues underlined are encoded by cloning
136 sites AgeI (TG) and SalI (AST). The codon optimised cDNA sequence is shown in supplementary
137 Information
138 C) SDS-PAGE gel of purified VHH(IH4)-RBD proteins. Three micrograms of protein were run on
139 4-12% Bolt Bis-Tris under reducing conditions. 1: IH4-RBD produced in house in Expi293F cells,
140 2: IH4-RBD produced by Absolute Antibody, Oxford in HEK293 cells.
141
142 **RESULTS**
143
144 **Production of the IH4-RBD Reagent**

145 The IH4-RBD sequence (Figure 1B) was codon optimised and expressed in Expi293F cells in a
146 standard expression vector (available on request). One advantage of this mode of production
147 compared to bacterially produced protein as used by Habib et al, is that the reagent will carry
148 the glycosylation moieties found in humans, which may play a role in the antigenicity of the
149 RBD (Pinto et al., 2020). The protein (with a 6xHis tag at the C-terminus for purification) was
150 purified by Ni-NTA chromatography which yielded ~160 mg/L. We later had one gram of the
151 protein synthesised commercially by Absolute Antibody, Oxford. The IH4-RBD protein ran as
152 single band at ~40 kDa on SDS PAGE (Figure 1C).
153
154 **Establishment of the Haemagglutination Test (HAT) with monoclonal antibodies to the RBD**
155 One purpose envisaged for the HAT is for use as an inexpensive Point of Care Test for
156 detection of antibodies in capillary blood samples obtained by a "finger-prick". We therefore
157 wished to employ human red cells as indicators without the need for cell separation or
158 washes, to mimic this setting. The use of V-bottom microtiter plates to perform simplified
159 hemagglutination tests was first described over 50 years ago (Wegmann & Smithies, 1966).
160 In preliminary tests, we observed that 50 µL of whole blood (K2EDTA sample) diluted 1:40 in
161 phosphate-buffered saline (PBS), placed in V-bottomed wells of a standard 96-well plate,
162 settled in one hour to form a button of red cells at the bottom of the well. The normal
163 haematocrit of blood is ~40% vol/vol, so this dilution provides ~1% red cells. If the plate was
164 then tilted, the red cell button flowed to form a "teardrop" in ~30 seconds (for example Figure
165 2A Row 8).
166
167 If serum or plasma samples are to be tested, a standard collection of 10 mL of Type O Rh-
168 negative (O-ve) blood into a K2EDTA tube will thus provide sufficient red cells for 8,000 test
169 wells.
170
171 A well characterised monoclonal antibody to the RBD, CR3022 (ter Meulen et al., 2006) added
172 to the red cells at between 0.5-32 ng/well in 50 µL, did not agglutinate the cells on its own
173 (Figure 2A Row 8). The addition of the IH4-RBD reagent at between 12.5-800 ng/well (in 50
174 µL PBS) induced a concentration dependent agglutination of the red cells, detected by the
175 formation of a visible mat or plug of agglutinated cells, and the loss of teardrop formation on
176 tilting the plate (Figure 2A). From repeated trials of this experiment we established that a

177 standard addition of 100 ng/well of the IH4-RBD developer (50 µL of a stock solution of 2
178 µg/mL in PBS) induced agglutination of 50 µL of 1:40 human red cells in the presence of as
179 little as 2 ng/well of the CR3022 monoclonal antibody. The standardised protocol used for the
180 subsequent tests were thus performed in 100 or 150 µL final volume, containing 100 ng of
181 the IH4-RBD developer, and 50 µL 1:40 whole blood (~1% v/v red cells ~ 0.5 µL packed red
182 cells per reaction). After 60 minutes incubation at room temperature, we routinely
183 photographed the plates after the 30 s tilt for examination and reading.
184
185 The requirement for 100 ng of the IH4-RBD developer per test well means that the gram of
186 IH4-RBD protein we have had synthesised is sufficient for 10 million test wells at a cost of
187 approximately 0.27 UK pence per test.



188
189 **Figure 2. Haemagglutination with human monoclonal antibodies or nanobodies to the**
190 **SARS-CoV-2 RBD**
191 A) Titration of IH4-RBD and monoclonal Antibody CR3022 to RBD. Doubling dilutions of
192 CR3022 and IH4-RBD were prepared in separate plates. 50 µL red cells (O-ve whole blood
193 diluted 1:40 in PBS) were added to the CR3022 plate, followed by transfer of 50 µL titrated
194 IH4-RBD. From this titration, 100 ng/well of IH4-RBD was chosen for detection.
195 B) Detection of other anti-RBD monoclonal antibodies and ACE2-Fc. Monoclonal antibodies
196 were prepared in doubling dilutions in 50 µL PBS from left to right, 50 µL of 1:40 O-ve red cells
197 were added, followed by 50 µL of IH4-RBD (2 µg/mL in PBS). The end point was defined as the
198 last dilution without tear drop formation on tilting the plate for ~ 30 s. The binding sites for
199 CR3022, EY6A and ACE2 on RBD have been defined (Huo, Zhao, et al., 2020; Lan et al., 2020;
200 Yan et al., 2020; Zhou et al., 2020). EW-9B and EW-9C are monoclonal antibodies against non-

201 RBD epitopes on the spike protein (Huang et al., 2020). ACE2-Fc has been described (Huang
202 et al., 2020).
203
204 Having established a standard addition of 100 ng/well of the IH4-RBD reagent, we screened a
205 set of twelve human monoclonal antibodies, two divalent nanobodies, and divalent ACE2-Fc,
206 that are known to bind to the RBD (Huang et al., 2020; Huo, Le Bas, et al., 2020; Pinto et al.,
207 2020; Wrapp et al., 2020; Zhou et al., 2020). These reagents bind to at least three independent
208 sites on the RBD, and some are strongly neutralising and capable of profound ACE2 blockade
209 (Huang et al., 2020; Huo, Le Bas, et al., 2020). Twelve of the 15 divalent molecules
210 agglutinated red cells and titrated in the HAT to an end point between 2-125 ng/well, after
211 addition of 100 ng IH4-RBD (Figure 2B and Supplementary Table 1). Two monoclonal
212 antibodies, FD-5D and EZ-7A (Huang et al., 2020) and one divalent nanobody VHH72-Fc
213 (Wrapp et al., 2020), failed to agglutinate red cells in the presence of the IH4-RBD reagent.
214 However, if a monoclonal antibody to human IgG was added to the reaction (50 µL of mouse
215 anti-human IgG, Sigma Clone GG5 1:100), these molecules specifically agglutinated the red
216 cells (Supplementary Figure 1A, B). This result, analogous to the "indirect" Coombs Test
217 (Coombs et al., 1945; Pamphilon & Scott, 2007), suggested that these three molecules had
218 bound to the RBD associated with the red cells but failed to crosslink to RBDs on neighbouring
219 red cells. However, these could be crosslinked by the anti IgG reagent. Monoclonal antibodies
220 to other regions of the spike protein (EW-9B, EW-9C and FJ-1C) failed to agglutinate red cells
221 (Figure 2B, Supplementary Table 1). Finally we looked at the effect of a divalent ACE2-Fc
222 molecule constructed by fusing the peptidase domain of ACE2 (amino acids 19-615) to the
223 hinge and Fc region of human IgG1 (described in (Huo, Le Bas, et al., 2020). ACE2-Fc
224 agglutinated red cells strongly in the presence of 100 ng/well of the IH4-RBD developer,
225 titrating to ~ 4 ng/well (Figure 2B rows 7,8).
226
227 In summary, these results showed that all of the known epitopes bound by characterised
228 monoclonal antibodies were displayed by the IH4-RBD reagent, as well as the ACE2 binding
229 site, and could mediate agglutination by specific antibodies, divalent nanobodies, or ACE2-Fc.
230
231 **Agglutination by plasma from donors convalescing from COVID-19**

232 These experiments established the conditions for detection of haemagglutination by
233 monoclonal antibodies to the RBD, in particular the optimum concentration of IH4-RBD of
234 100 ng/well. We then proceeded to look for haemagglutination by characterised plasma from
235 COVID-19 convalescent donors. In the first trial we tested eighteen plasma samples from
236 patients with mostly mild illness, that had been characterised with a quantitative ELISA to
237 detect antibodies to the RBD (Peng et al., 2020). For these experiments we used fresh O-ve
238 blood (K2EDTA sample) diluted to 1:40 as a source of red cells to avoid agglutination by
239 natural agglutinins in the plasma. Plasmas were titrated by doubling dilution from 1:20 in 50
240 µL, then 50 µL of 1:40 O-ve red cells were added, followed by addition of 100 ng of the IH4-
241 RBD in 50 µL PBS. After one-hour incubation, plates were tilted for ~30 seconds,
242 photographed and read. The titre of agglutination was assessed by complete loss of teardrop
243 formation by the red cells, any formation of a teardrop was regarded as negative. Figure 3A
244 shows that the HAT titre matched the RBD ELISA results. Four samples were scored as
245 negative in both assays. The remaining results showed that in general the HAT titre increased
246 with the ELISA end point titre. One sample gave a positive titre of 1:320 in the HAT but was
247 negative in ELISA (indicated with an arrow). We investigated this sample with a developer
248 composed of the IH4 nanobody without the RBD component, which revealed that
249 agglutination was RBD dependent (not shown). This sample was also positive at 1:1123 in an
250 ELISA for full length spike protein (not shown). The highest titre detected in these samples by
251 the HAT was 1:1280 (Figure 3B).
252
253 These preliminary results showed that the HAT could detect antibodies to the RBD in plasma
254 samples from convalescent patients in a similar manner to an ELISA test, but were not
255 sufficient to establish the sensitivity and specificity of the HAT.

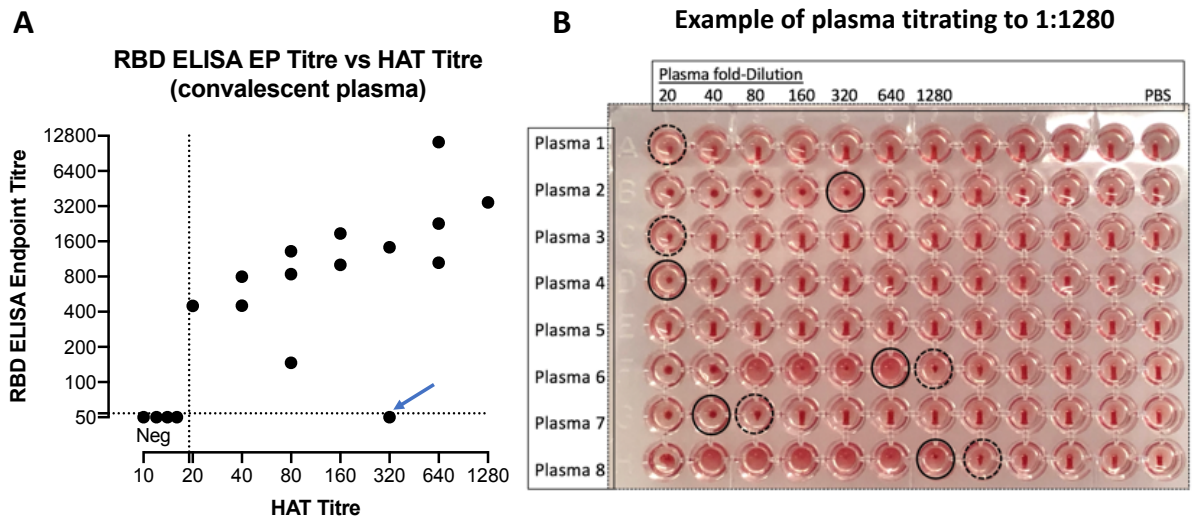


Figure 3. Titration of stored plasma in the agglutination assay.

A) Eighteen plasma samples from mild cases were compared for titration in the HAT with 1:40 O-ve whole blood from a seronegative donor, and endpoint titre in an RBD ELISA (Peng et al., 2020)). Four samples were negative in both assays. The data point marked with an arrow on the graph (plasma 2 on the plate, Fig 3B) was checked with a reagent composed of IH4 without RBD and shown to be dependent on antibodies to the RBD. This sample did score positive for antibodies to full length spike in an ELISA (EPT 1:1123).

B) An example of titration: positive agglutination endpoints (loss of teardrop) are marked with a black solid-line circle, partial teardrops are marked with a dotted-line circle.

Sensitivity and specificity of the Haemagglutination Test

To formally assess the sensitivity and specificity of the HAT we collected a set of 98 “positive” plasma samples from donors diagnosed with COVID-19 by RT-PCR at least 28 days prior to sample collection (NHS Blood and Transplant), and 199 “negative” serum samples from healthy donors from the pre-COVID-19 era (Oxford Biobank). The samples were randomised before plating. The test wells were arranged in duplicate to contain serum/plasma at 1:40 dilution, and 1:40 O-ve red cells in 50 µL. 100 ng of IH4-RBD in 50 µL PBS was added to one well of the pair, 50 µL of PBS to the other (as a negative control). The negative control is important because in rare cases, particularly in donors who may have received blood transfusions, the sample may contain antibodies to non-ABO or Rhesus D antigens. After development, the plates were photographed, and read by two independent masked observers. Complete loss of teardrop was scored as positive, any flow in the teardrop as

negative. These rules were established before setting up the tests. Disagreements (7% overall) were resolved by accepting the weaker interpretation – i.e. if one observer scored positive but the other negative, the well was scored as negative. Having completed the scoring the columns of samples were re-randomised and the test and scoring repeated.

Examples of test wells and scoring are shown in Figure 4. The red cells in the negative control (PBS) wells formed a clear teardrop. Red cells in positive wells (indicated with a solid ring) settled either into a mat or a button that failed to form any teardrop on tilting for 30 seconds. Occasional wells (15 of 297) formed a “partial” teardrop (shown by a dashed ring). These were scored as negative by prior agreement.

With these rules in place we obtained in the first run sensitivity 88%, specificity 99%, and in the second run sensitivity 93%, specificity 99% (Figure 4). The Siemens Atellica Chemiluminescence assay for detection of IgG antibodies to the RBD was run in parallel on 293 of these 297 samples and gave sensitivity 100%, specificity 100% for this sample set.

We decided prior to this formal assessment to score wells with partial teardrop formation as negative, as these wells tended to give rise to disagreements between scorers and were not very helpful. Fifteen of 297 wells gave a partial teardrop. Six of these fifteen were from PCR-ve donors and scored negative on the Siemens assay, 9/16 were from PCR+ve donors and were Siemens positive. If partial teardrops were scored as positive, the sensitivity of the two assays increased to 97% and 99% (from 88% and 93%), but specificity was reduced to 96% and 98% (from 99%). This small loss of specificity would be unacceptable in sero-surveys where the expected prevalence of previous SARS-CoV-2 infection was low.

Figure 4. Operating characteristics of the HAT.

A) The test set of 297 randomised plasma samples were diluted 1:40 mixed with 1:40 O-ve blood in two columns. IH4-RBD (100 ng in 50 µL) was added to the test samples, and PBS to negative control wells. The plates were incubated at room temperature for one hour to allow the red cell pellet to form, then tilted for ~30 seconds to allow a teardrop to form. Complete loss of teardrop was scored as positive agglutination (marked with a black solid-line circle). Full teardrop or partial teardrop (marked with a dotted-line circle) were scored negative. The samples in columns were re-randomised and tested for a second time two days later.

B) Contingency table showing the operating characteristics of the HAT.

HAT in the Hospital Setting

We next assessed the HAT in the setting of patients recently admitted to hospital (the first five days) through access to the COMBAT collection of samples (see methods). This set comprised 153 plasma samples from donors diagnosed with COVID-19 by PCR, with clinical syndromes classified as « Critical », « Severe », « Mild », and «PCR positive Health Care Workers ». Seventy-nine control plasma samples donated in the pre-COVID-19 era were

321 obtained either from patients with bacterial sepsis (54 samples), or healthy volunteers (25
322 samples). Samples were titrated in 11 doubling dilutions of 50 µL from 1:40 – 1:40,096
323 (columns 1-11). Column 12 contained 50 µL PBS as a negative control. 50 µL of 1:40 O-ve
324 whole blood was added, followed by 50 µL of 2 µg/mL IH4-RBD (100 ng/well). In parallel, all
325 of the 153 samples from PCR positive donors were assessed by the Siemens Atellica
326 Chemiluminescence test for antibodies to the RBD of the spike protein. The HAT scores (as
327 the number of doubling dilutions of the sample required to reach the endpoint of complete
328 loss of teardrop), and representative agglutination results are shown in figure 5A. In Figure
329 5B the HAT scores are plotted with their related Siemens test scores.
330
331 None of the seventy-nine negative control samples scored as positive in the HAT at a dilution
332 of 1:40, thus providing 100% specificity in this set of samples. The HAT detected 131/153 (86%
333 sensitivity) of the samples from PCR-diagnosed donors within the first five days of hospital
334 admission, whereas the Siemens test detected 113/153 (74%). On day 5 the HAT detected
335 41/45 (91% sensitivity). Two samples had an endpoint greater than 11 doubling dilutions in
336 the HAT, and required a repeat measurement spanning two plates. These two samples
337 titrated to 13 doubling dilutions (1: 163,840). Unmasking the samples revealed that both were
338 acquired from an elderly lady with mild disease on days 3 and 5 of her admission. The range
339 of positive titres detected by HAT was broad: 1 to 13 doubling dilutions (1:40 – 1:163,840). A
340 correlation coefficient with the Siemens test could not be calculated as the latter has a ceiling
341 score of 10 (Figure 5B). A comparison of the two tests in a contingency table with cut-off of
342 1:40 (first doubling dilution) for HAT, and a score ≥ 1 for the Siemens test (as defined by the
343 manufacturer), showed a strong correlation between the two tests for detection of antibodies
344 to the RBD ($P < 0.0001$; two-tailed Fisher's exact test, Figure 5B). Fifty-four of the 153 samples
345 were from 25 donors with COVID-19 from whom repeated samples were taken on days 1, 3,
346 or 5 of admission. The HAT detected a rise in agglutination titre over the first five days of
347 admission in 17/25 (68%) of these patients (Table 1). Reductions in titre were not detected.

	Critical	Severe	Mild	HCW	Sepsis	Healthy
N samples	32	62	39	20	54	25
N donors	24	48	32		43	

Donors were grouped according to clinical criteria; HCW = Front Line Health Care Workers; Sepsis = Samples with patients with Sepsis prior to Covid-19 pandemic; Healthy = Healthy volunteers prior to Covid-19; DD 1 = 1:40. Actual Titre = 20 x 2^DD.

	HAT+	HAT-	Total	Fraction

Comments

Of 22 Samples –ve in HAT, 10 were collected on Day 1

Of 20 samples –ve in both assays, 9/20 were collected on Day 1

Figure 5. Titration of the set of 232 samples in the HAT

A) The collection included 32 samples from 24 Critical patients, 62 samples from 48 Severe, 39 samples from 32 Mild, 20 single samples from health care workers (HCW), 54 samples from 43 patients with unrelated sepsis in the pre-COVID-19 era, 25 samples from healthy unexposed controls. Median is indicated by a red line. DD: doubling dilutions.

B) Comparison to Siemens Result (anti RBD) with HAT titre by doubling dilution for 153 samples from Critical, Severe, Mild and HCW SARS-CoV-2 PCR positive donors.

These results showed that in the setting of hospital admission in the UK for suspected COVID-19 disease, the HAT has an overall sensitivity of 86% and specificity of 100% by day five, and frequently (68%) detected a rise in HAT titre during the first five days of admission. In this context the HAT performed at least as well as the commercially available Siemens Atellica Chemiluminescence assay (74%) for the detection of antibodies to the RBD of SARS-CoV-2 spike protein. Twenty samples were negative in both tests, but nine of these were taken on

363 day 1 of admission, which suggests that both tests have lower detection levels early in the
364 course of hospital admission, before the antibody response has fully developed.
365
366 The O-ve blood used as indicator for this experiment was collected into a heparin tube, and
367 then transferred to a K2EDTA tube. In order to be sure that the presence of heparin in the red
368 cells had not altered the behaviour of the test, and to confirm the robustness of the results,
369 we repeated the titrations on all of the 232 samples 34 days later, with fresh O-ve red cells
370 from a different donor collected as usual into a K2EDTA tube. The results are shown in
371 supplementary figures 2A-C. Specificity of the HAT remained at 100% (none of the 79 control
372 samples were detected as positive at 1:40). The correlation with the previous assay was
373 strong (R^2 = 0.975), and 99% of the 232 titrations were within one doubling dilution of the
374 matched earlier measurement. The slope of the correlation was 0.94 (95% CI 0.92-0.96),
375 significantly less than 1. This was due to a proportion of results titrating to one doubling
376 dilution lower titre. However, this had only a small impact on sensitivity (81% from 86%),
377 which was still an improvement on the Siemens test (74%) in this context of the first five days
378 of hospital admission.

398

399 **HAT as a Point of Care Test on Capillary Samples**

400 The HAT is designed to detect antibodies to the RBD starting at a serum dilution of 1:40, and
401 we have found that that 50 µL of 1:40 dilution of whole blood provides an optimal
402 concentration of red blood cells for detection by agglutination in V-bottomed 96 well plates.
403 We have not completed an extensive analysis of the HAT as a Point of Care Test. However,
404 we have preliminary evidence that lyophilised IH4-RBD sent to the National Institute of
405 Immunology, New Delhi, functions as a Point of Care Test on capillary blood obtained by
406 finger-prick. In Figure 6, three positive (donors 1, 2 and 3) and three negative (donors 4, 5 and
407 6) HAT results are compared to a standard ELISA for detection of antibodies to the RBD.

408

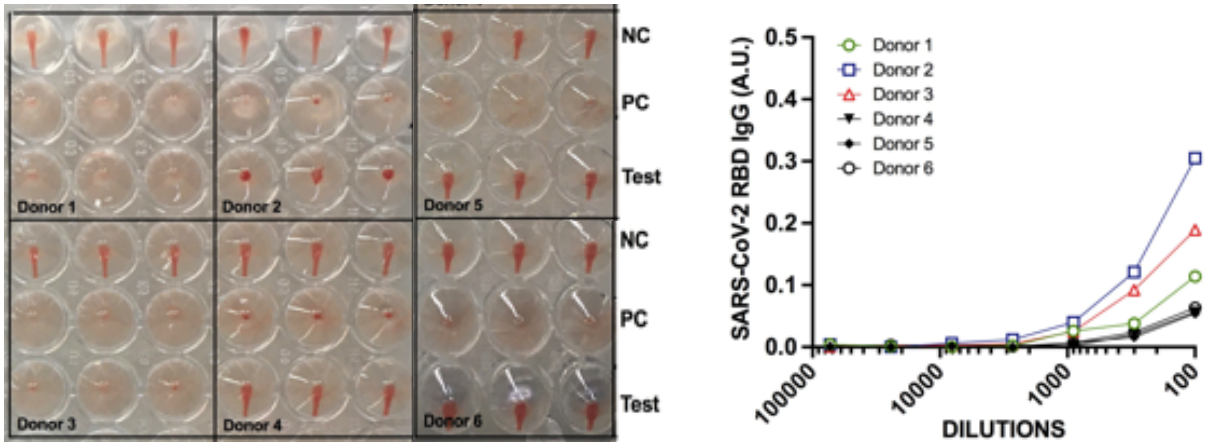

Figure 6. HAT as a point of care test.

Capillary blood samples were obtained by lancet. Antibodies to the RBD were detected by HAT on autologous red cells in the sample in "Test" wells (plasma at 1:40) after addition of 100 ng/well IH4-RBD (see methods). NC, Negative Control (PBS replaces IH4-RBD); PC Postive Control (20 ng/well CR3022, an anti-RBD monoclonal antibody added). In parallel, after removal of red cells, the plasma was tested in a standard ELISA for detection of antibodies to the RBD. Low levels of antibody detected in the ELISA were sufficient to give a positive result in the HAT.

Further work is needed to establish the operating characteristics of the HAT as a Point of Care Test on capillary samples. We provide a suggested operating procedure for capillary samples in methods.

Distribution of the IH4-RBD as lyophilised protein

In order to ship the IH4-RBD reagent efficiently we have examined the effects of lyophilisation and reconstitution with water. IH4-RBD synthesised for the purpose of distribution was provided at 5 mg/mL in PBS by Absolute Antibody Ltd, Oxford. Two hundred microlitre aliquots (1 mg, enough for 10,000 test wells) were lyophilised overnight and stored at -20 °C. Aliquots were thawed, reconstituted with 200 µL double distilled water and titrated against the pre-lyophilisation material. No change in the titration occurred. We have synthesised one gram of IH4-RBD, sufficient for 10 million test wells. This is available free of charge for any qualified group anywhere in the world in aliquots of 1 mg (20,000 test wells).

433 **DISCUSSION**

434

435 The COVID-19 pandemic has had a particularly gruelling influence on the world economy, and
436 on most populations of the world. The appearance of such a new highly contagious virus will
437 probably not be a unique occurrence in the decades ahead. One of the lessons learned is the
438 importance of developing affordable serological tests for detection of immune responses to
439 SARS-CoV-2. Commercial antibody tests are not widely available to low- and middle-income
440 countries, and lateral flow assays, while offering early promise as a near-patient test, have
441 failed to deliver in terms of performance metrics, are expensive, and there are concerns about
442 significant batch-to-batch variation (Adams et al., 2020). By contrast, the advantages of the
443 HAT are the low cost of production of its single reagent (~0.27 UK pence per test well), better
444 performance than most lateral flow devices (Adams et al., 2020), and versatility in not
445 requiring anything other than a source of O-ve blood (10 mL of K2EDTA blood provides
446 enough for 8,000 tests), an adjustable pipette, PBS, and a standard 96 well V-bottomed plate.

447

448 We have demonstrated that the HAT functions as a viable test for the presence of antibodies
449 to the RBD of the SARS-CoV-2 spike protein in stored serum/plasma samples, using O-ve red
450 cells as indicators. In the formal assessment of sensitivity and specificity we recorded an
451 average 90% sensitivity and 99% specificity (Likelihood Ratio ~175), compared to 100%
452 sensitivity and 100% specificity for the Siemens Atellica Chemiluminescence test on the same
453 set of samples. The "positive" samples were selected to have been taken at least 28 days after
454 a positive PCR test. These conditions are optimal for serological tests by allowing time for a
455 rise in antibodies. The sensitivity of ~90% and specificity of 99% did not reach the level of
456 98% for both recommended by the UK MHRA (The National SARS-CoV-2 Serology Assay
457 Evaluation Group, 2020), or 99.5% for both recommended by the Infectious Disease Society
458 of America (Hanson et al., 2020). However, these values are still consistent with a useful test
459 in appropriate contexts, provided that users are fully aware of the operating characteristics
460 and interpret the results correctly.

461

462 The sensitivity of the single point HAT can be enhanced (to ~98%) if wells with partial teardrop
463 formation are scored as positive. However, this improvement in sensitivity is gained at the
464 expense of a reduced specificity (to ~97%). If partial teardrops are to be scored as positive in

465 the spot test at 1:40, we recommend obtaining confirmation for these by ELISA. Improvement
466 in the operating characteristics of the HAT may be possible by a systematic analysis of buffer
467 composition and experimental conditions, and is being investigated. We have deliberately
468 kept complexity to a minimum, and thus all dilutions were made in standard PBS, and for the
469 moment we recommend scoring wells with partial teardrop formation as negative.
470
471 It is interesting that the HAT titrations actually performed a little better than the Siemens test
472 on 153 stored plasma samples from donors during the first five days of their hospital
473 admission (note that symptom onset may have been several days earlier), in whom it
474 detected 86% (81% in the repeat) of samples from PCR-diagnosed donors, compared to 74%
475 for the Siemens test, and gave 100% specificity for the sample set containing control plasma
476 from patients with sepsis and healthy controls. We speculate that at this early period of the
477 COVID-19 illness the immune response may be dominated by IgM that would be expected to
478 be particularly efficient at crosslinking the IH4-RBD labelled red cells. In addition, of the
479 twenty-five donors who were tested more than once in the first five days in hospital, the HAT
480 detected a rise in titre in seventeen (68%). A fixed high titre was detected in a further five to
481 provide a sensitivity of 88% in these twenty-five cases. In situations of high clinical suspicion,
482 the HAT could potentially have a place as a helpful test to support the diagnosis of COVID-19
483 by detecting a rising titre of antibodies to the RBD during hospital admission. In patients with
484 a prior probability of a diagnosis of COVID-19 of ~10%, the likelihood ratio of ~175 for the HAT
485 provides a posterior probability of ~95% for this diagnosis. However, it is essential that if
486 clinicians use a rising titre in the HAT as a diagnostic aid, they should be aware of the relatively
487 low sensitivity (~68%) in this context.
488
489 With a specificity of 99%, the HAT could be employed for epidemiological surveys of the
490 seropositive rate in stored serum/plasma samples from populations with a moderate
491 expected prevalence ~10%, which would entail a negative predictive value of ~90%. The HAT
492 may be useful to detect seroconversion after vaccination, and for the identification of
493 potential donors of high titre plasma for therapy, if the clinical trials that are in progress
494 demonstrate a benefit. In the absence of knowledge about the level of antibody that indicates
495 protection, the HAT should not be used to provide personal results to individuals, as discussed
496 by the UK Royal College of Pathologists (https://www.rcpath.org/profession/on-the-

497 agenda/COVID-19-testing-a-national-strategy.html). Finally, we show that the lyophilised
498 IH4-RBD reagent sent to New Delhi functioned as expected in preliminary point of care testing
499 on capillary samples obtained by finger-prick. However, additional evidence is needed to
500 show that the sensitivity and specificity of the HAT, applied as a Point of Care Test in this way,
501 are comparable to the tests on stored plasma samples, as stressed by the IDSA guideline on
502 serological testing (Hanson et al., 2020). This will need to be done in field conditions, which is
503 planned.
504
505 The technique required for applying the HAT can be learned in a day by a trained laboratory
506 technician, paramedic, nurse or doctor. We have produced one gram of the developing IH4-
507 RBD reagent (enough for ten million test wells) and offer to ship lyophilised aliquots of this
508 material (sufficient for 10,000 tests) anywhere in the world, free of charge, for use as a
509 research reagent for serological studies of COVID-19.
510
511 **METHODS**
512
513 **Sample Collection and Ethics**
514 **Figures 1,2:** Control whole blood (K2EDTA) as a source of red cells was collected from a
515 healthy donor after informed consent.
516
517 **Figure 3:** Pre-pandemic negative controls: these samples were collected from healthy adults
518 in the Oxfordshire region of the UK between 2014 and 2016, ethics approval: Oxfordshire
519 Clinical Research Ethics Committee 08/H0606/107+5. Positive sample set: these were
520 convalescent plasma donors recruited by NHS Blood and Transplant (NHSBT), ethics approval
521 (NHSBT; RECOVERY [Cambridge East REC (ref: 20/EE/0101)] and REMAP-CAP [EudraCT 2015-
522 002340-14] studies).
523
524 **Figures 4, 5 and Table 1:** Known COVID-19 positive samples were collated from three ethically
525 approved studies: Gastro-intestinal illness in Oxford: COVID substudy [Sheffield REC,
526 reference: 16/YH/0247]ISARIC/WHO, Clinical Characterisation Protocol for Severe Emerging
527 Infections [Oxford REC C, reference 13/SC/0149], the Sepsis Immunomics project [Oxford REC
528 C, reference:19/SC/0296]) and by the Scotland A Research Ethics Committee (Ref:

529 20/SS/0028). Patients were recruited from the John Radcliffe Hospital in Oxford, UK, between
530 March and May 2020 by identification of patients hospitalised during the SARS-COV-2
531 pandemic and recruited into the Sepsis Immunomics and ISARIC Clinical Characterisation
532 Protocols. Time between onset of symptoms and sampling were known for all patients and if
533 labelled as convalescent patients were sampled at least 28 days from the start of their
534 symptoms. Written informed consent was obtained from all patients. All patients were
535 confirmed to have a test positive for SARS-CoV-2 using reverse transcriptase polymerase
536 chain reaction (RT-PCR) from an upper respiratory tract (nose/throat) swab tested in
537 accredited laboratories. The degree of severity was identified as mild, severe or critical
538 infection according to recommendations from the World Health Organisation. Severe
539 infection was defined as COVID-19 confirmed patients with one of the following conditions:
540 respiratory distress with RR>30/min; blood oxygen saturation<93%; arterial oxygen partial
541 pressure (PaO2) / fraction of inspired O2 (FiO2) <300 mmHg; and critical infection was defined
542 as respiratory failure requiring mechanical ventilation or shock; or other organ failures
543 requiring admission to ICU. Comparator samples from healthcare workers with confirmed
544 SARS-CoV-2 infection who all had mild non-hospitalised disease were collected under the
545 Gastro-intestinal illness in Oxford: COVID sub-study, and samples from patients with
546 equivalently severe disease from non-COVID infection were available from the Sepsis
547 Immunomics study where patients presenting with significantly abnormal physiological
548 markers in the pre-pandemic timeframe had samples collected using the same methodology
549 as that applied during the COVID pandemic. Blood samples were collected in K2EDTA
550 vacutainers and PBMCs were separated from plasma using Sepmate isolation tubes
551 (STEMCELL Technologies) and plasma was used in the downstream HAT assay.
552
553 **Figure 6:** Capillary samples were collected from members of institute staff with informed
554 consent (New Delhi, India). The study is a part of the COVID-19 project 'IPA/2020/000077'.
555 The project has been approved by the Institutional Human Ethics Committee; Ref. no. -
556 IHEC#128/20.
557
558 **Cloning, Expression and Purification of VHH(IH4)-RBD**
559 The codon-optimised gene encoding IH4-RBD sequence (Figure 1B and supplementary for the
560 cDNA sequence) was synthesized by Integrated DNA Technologies. The gene was cloned in

561 to the AbVec plasmid (Genbank FJ475055) using the restriction sites AgeI and HindIII (the
562 vector supplied the signal sequence). **This expression plasmid for IH4-RBD is available on**
563 **request.** Protein was expressed in Expi293F^{TM} cells using the manufacturer's protocol
564 (Thermo Fisher). Protein supernatant was harvested on day 5/6 after transfection, spun and
565 0.22 µm filtered. The protein was affinity-purified using a His-Trap HP column (Cytiva). Binding
566 buffer consisted of 20 mM Sodium Phosphate, 150 mM NaCl and 20 mM Imidazole at pH 7.4,
567 and the elution buffer of 500 mM Imidazole in 1 x binding buffer. Protein was concentrated
568 using 15 ml Vivaspin 30 kDa MWCO filter and then buffer exchanged to PBS using a 10 ml 7
569 kDa Zebaspin column (Thermo Fisher).
570
571 For large scale production, the protein was synthesized by Absolute Antibody Ltd, Oxford
572 using the same plasmid construct in HEK293 cells.
573
574 **Lyophilisation of IH4-RBD and CR3022 monoclonal antibody**
575 For lyophilisation, 200 µL (1 mg) of IH4-RBD (5 mg/mL) and 100 µL (200 µg) CR3022 mAb (2
576 mg/mL) in PBS buffer prepared in Protein Lo-Bind microcentrifuge tube (Fisher Scientific)
577 were frozen at -80 °C and further cooled down to - 196 °C using liquid nitrogen. Pre-cooled
578 samples were transferred to Benchtop K freeze-dryer (VirTis) with chamber at 49 µbar and
579 condenser pre-cooled to -72.5 °C. The samples were freeze-dried for a minimum of 24 h,
580 wrapped in Parafilm (Merck) and stored at -20 °C. Lyophilised sample was reconstituted in
581 the same original volume of MilliQ water.
582
583 **Indirect ELISA to detect SARS-CoV-2 specific IgG (Figure 6)**
584 A standard indirect ELISA was used to determine the SARS-CoV-2 specific IgG levels in plasma
585 samples. A highly purified RBD protein from SARS-CoV-2 Wuhan strain (NR-52306, BEI
586 Resources, USA), expressed in mammalian cells, was used to capture IgG in the plasma
587 samples. Briefly, ELISA plates (Nunc, Maxisorp) were coated with 100 µL/well of RBD antigen
588 diluted in PBS (pH 7.4) at the final concentration of 1 µg/mL and incubated overnight at 4°C.
589 Plates were washed three times with washing buffer (0.05% Tween-20 in PBS) followed by
590 the incubation with blocking buffer (3% Skim milk and 0.05% Tween-20 in PBS). The 3-fold
591 serially diluted heat inactivated plasma samples in dilution buffer (1% Skim milk and 0.05%
592 Tween-20 in PBS) were added into the respective wells, followed by incubation at room

593 temperature for 1 hour. After incubation, plates were washed, and anti-human IgG
594 conjugated with Horseradish Peroxidase (HRP) (Southern Biotech) was added in each well.
595 After 1 h incubation, plates were washed and developed by OPD-substrate (Sigma-Aldrich) in
596 dark at room temperature. The reaction was stopped using 2N HCl and the optical density
597 (OD) was measured at 492 nm. The RBD-antigen coated wells that were added with sample
598 diluent alone were used as the blank. The OD values from sample wells were plotted after
599 subtracting the mean of OD values obtained in the blank wells.
600
601 **Equipment and Reagents for HAT**
602 • O-ve blood as a source of red cells collected in K2EDTA tube, diluted **in PBS to 1:20 or**
603 **1:40 as needed.** Resuspend by inverting gently ~12 times.
604 • BD Contact Activated Lancet Cat. No. 366594 (2 mm x 1.5 mm)
605 • 100 µL, 20 µL pipettes, Multichannel pipettes
606 • V-bottomed 96-well plates (Greiner Bio-One, Cat. No. 651101, Microplate 96-well, PS,
607 V-bottom, Clear, 10 pieces/bag)
608 • Eppendorf Tubes
609 • K2EDTA solution (add 5 mL PBS to 10 mL K2EDTA blood collection tube = 3.6 mg
610 K2EDTA/mL, store at 4 °C)
611 • Phosphate Buffered Saline Tablets (OXOID Cat. No. BR0014G)
612 • IH4-RBD Reagent diluted 2 µg/mL in PBS. This remains active for at least 1-2 weeks
613 stored at 4 °C
614 • V-bottomed 96-well plates, numbered, dated, timed (helps when timing many plates)
615 • Positive control monoclonal antibody CR3022 diluted to 2 µg/mL in PBS
616
617 **Other Reagents**
618 Monoclonal antibody to human IgG (Gamma chain specific) Clone GG-5 Sigma Cat. No. I5885
619
620 **1. Spot test on Stored Serum/Plasma samples (Figure 4).**
621 1. Plate out 50 µL of **1:20** serum/plasma in alternate columns 1,3,5,7,9,11 (add 2.5 µL
622 sample to 47.5 µL PBS).

2. Add 50 µL **1:20** O-ve blood collected in (**so that now sample is diluted to 1:40 and red cells at ~1% v/v**)
3. Mix and transfer 50/100 µL to neighbouring columns 2,4,6,8,10,12 for -ve controls. The negative control is important because in rare cases, particularly in donors who have received blood transfusions, the sample in principle may contain antibodies to non-ABO or Rhesus D antigens.
4. Add 50 µL IH4-RBD reagent (2 µg/mL in PBS = 100 ng/well) to Columns 1,3,5,7,9,11
5. Add 50 µL PBS to columns 2,4,6,8,10,12.
6. Inc 1 hr RT
7. Tilt for 30 seconds
8. Photograph: with mobile phone use the zoom function to obtain a complete field
9. Read as Positive = No teardrop, Negative <1:40 = partial teardrop, Neg = complete teardrop.
10. Two readers should read the plates independently, and disagreements resolved by taking the lesser reading.
11. For each batch of samples set up positive control wells containing 20-100 ng monoclonal antibody CR3022 (as in Finger-Prick test below). This establishes that all of the reagents are working.

2. Titration of Stored Serum/Plasma Samples.

1. Dilute samples to **1:20** in 50 µL PBS (2.5 µL to 47.5 µL) in V-bottomed plate in Rows A-H, column 1.
2. Prepare doubling dilutions with PBS across the plate columns 1-11 (1:40 to 1:40,960), PBS control in column 12. Eight samples can be titrated per 96-well plate.
3. Add 50 µL 1:40 O-ve red cells (1% v/v or 1:40 fresh EDTA O-ve blood sample) to all wells
4. Add 50 µL IH4-RBD (2 µg/mL, = 100 ng/well). [Note: the red cells and IH4-RBD can be pre-mixed and added together in either 50 µL or 100 µL volume, to save a step. This variation in technique does not alter the measured titres.]
5. Allow red cells to settle for 1 hr
6. Tilt plate for at least 30 s and photograph. The titre is defined by the last well in which the tear drop fails to form. Partial teardrop regarded as negative.

655

656 **3. Finger-prick test on capillary blood as a Point of Care Test**

657 1. Preparation: Clean Hands, warm digit. Prepare a plate (96-well V-bottomed) labelled
658 with Date and Time.
659 2. Prick skin on outer finger pulp with disposable, single use BD or another Lancet.
660 3. Wipe away first drop of blood with sterile towel/swab
661 4. Massage second drop
662 5. Take a minimum of 5 µL blood with 20 µL pipette, mix immediately into 20 µL K2EDTA
663 (3.6 mg/mL/PBS) in Eppendorf. If possible, take 20 µL of blood and mix into 80 µL
664 K2EDTA solution. Another approach is collection of blood drops into a BD Microtainer
665 K2E EDTA lavender vials that take 250-500 µL.
666 6. For 5 µL sample dilute to 200 µL with PBS (add 175 µL PBS), for 20 µL sample dilute to
667 800 µL (add 700 µL PBS). ***Sample is now at 1:40, and the red cells are at the correct***
668 ***density (~1% v/v assuming a haematocrit of 40%) to give a clear tear drop***.
669 7. Plate 50 µL x 3 in V bottomed microtitre wells labelled T (Test), + (PC, positive Control),
670 - (NC, negative control) – see figure 6.
671 8. Add 10 µL of control anti RBD Mab CR3022 (2 µg/mL stock in PBS, 20 ng/well) to "+"
672 well
673 9. Add 50 µL IH4-RBD (2 µg/mL in PBS) to "T" (Test) and "+ve" wells, 50 µL PBS to "-ve"
674 well.
675 10. Incubate 1 hour at RT for Red Cells to form a pellet in the "-ve" well
676 11. Tilt plate against a well-lit white background for ~30 seconds to allow Tear drop to
677 form in "-ve" well.
678 12. The presence of antibodies to RBD is shown by loss of Tear Drop formation in the "T"
679 and "+ve" wells. Occasionally a partial tear drop forms – these wells are counted as
680 Negative.
681 13. **Photograph the plate to record the results with the date and time**. Results can be
682 reviewed and tabulated later. Taking picture from a distance and using the zoom
683 function helps to take a clear picture of all wells in a 96-well plate.
684 14. The negative (PBS) control should be done on every sample for comparison. The
685 Positive control induced by CR3022 is used to check that all the reagents are working,
686 and that the glycophorin epitope recognised by VHH(IH4) is present on the red cells.

687 Absence of the IH4 epitope should be *very rare* (Habib et al., 2013). For setting up
688 cohorts a positive control on every sample is therefore not necessary but should be
689 included in every *batch* of samples.
690 15. If a 20 µL sample of blood was taken from the finger prick there should be 650 µL of
691 the 1:40 diluted blood left. The red cells can be removed and a preparation of 1:40 O-
692 ve red cells used as above to titrate the sample. In principle the autologous red cells
693 could be washed repeatedly, resuspended in the same volume of PBS, and used as
694 indicators for the titration, however we have not attempted to do this. The s/n is 1:40
695 plasma that can be used in confirmatory ELISA or other tests.
696
697 **Author Contributions**
698 **Conceived, initiated and followed the project, documented portability and robustness of**
699 **HAT method in a separate laboratory, recruited collaborators:** Etienne Joly.
700 **Designed and produced the IH4-RBD reagent, established conditions for lyophilisation,**
701 **isolated and expanded human monoclonal antibodies to the RBD and ACE2-Fc, performed**
702 **the standard HAT assays, wrote the paper:** Alain Townsend, Pramila Rijal, Julie Xiao, Tiong
703 Kit Tan, Lisa Schimanski, Jiangdong Huo, Rolle Rahikainen, Kuan-Ying A Huang.
704 **Contributed examples of HAT as a Point of Care Test:** Nimesh Gupta.
705 **Provision of Serum/Plasma Sample Sets for Figure 4: Project management for Oxford**
706 **serology work for sensitivity and specificity measurement, assessment of preliminary data:**
707 Philippa Matthews, Derrick Crook, Sarah Hoosdally, Nicole Stoesser; **collection and**
708 **processing of samples, coordination of sample banks and running Siemens assay, ethics,**
709 **storage of pre-pandemic samples, coordination of provision of pre-pandemic samples from**
710 **Oxford BioBank, and sero-positive donors through NHSBT :** Teresa Street, Justine Rudkin,
711 Fredrik Karpe, Matthew Neville, Rutger Ploeg, David J Roberts, Abbie Bown, Richard Vipond,
712 Marta Oliveira, Abigail A Lamikanra, Hoi Pat Tsang.
713 **Provision of Serum Sample Sets for Figure 5 and Table 1 (COMBAT samples):** Alexander J
714 Mentzer, Julian C Knight, Andrew Kwok, Paul Klenerman, Christina Dold; **ISARIC4C**
715 **Investigators:** J. Kenneth Baillie, Shona C Moore, Peter JM Openshaw, Malcolm G Semple,
716 Lance CW Turtle; **Oxford Immunology Network Covid-19 Response Clinical Sample**
717 **Collection Consortium:** Mark Ainsworth, Alice Allcock, Sally Beer, Sagida Bibi, Elizabeth
718 Clutterbuck, Alexis Espinosa, Maria Mendoza, Dominique Georgiou, Teresa Lockett, Jose

Martinez, Elena Perez, Veronica Sanchez, Giuseppe Scozzafava, Alberto Sobrinodiaz, Hannah Thraves.

ACKNOWLEDGEMENT AND FUNDING

A.T. is funded by the Medical Research Council (MR/P021336/1), Townsend-Jeantet Charitable Trust (charity number 1011770) and the Chinese Academy of Medical Sciences (CAMS) Innovation Fund for Medical Science (CIFMS), China (grant no. 2018-I2M-2-002). N.G. is funded by the Science Engineering Research Board, Department of Science and Technology, India. P.C.M. is funded by the Wellcome Trust (grant ref 110110Z/15/Z). D.R. is supported by NIHR Oxford Biomedical Research Centre. National Institute for Health Research Biomedical Research Centre Funding Scheme (to G.R.S.), the Chinese Academy of Medical Sciences (CAMS) Innovation Fund for Medical Science (CIFMS), China (grant number: 2018-I2M-2-002). G.R.S. is supported as a Wellcome Trust Senior Investigator (grant 095541/A/11/Z).

The Spike Glycoprotein Receptor Binding Domain (RBD) from SARS-Related Coronavirus 2 Wuhan-Hu-1 (Figure 6), Recombinant from HEK293 Cells, NR-52306 was produced under HHSN272201400008C and obtained through BEI Resources, NIAID, NIH.

We thank the healthy volunteers who kindly donated their O-ve red cells for titration of samples.

DECLARATION

Competing Interests none.

848 **SUPPLEMENTARY DATA**

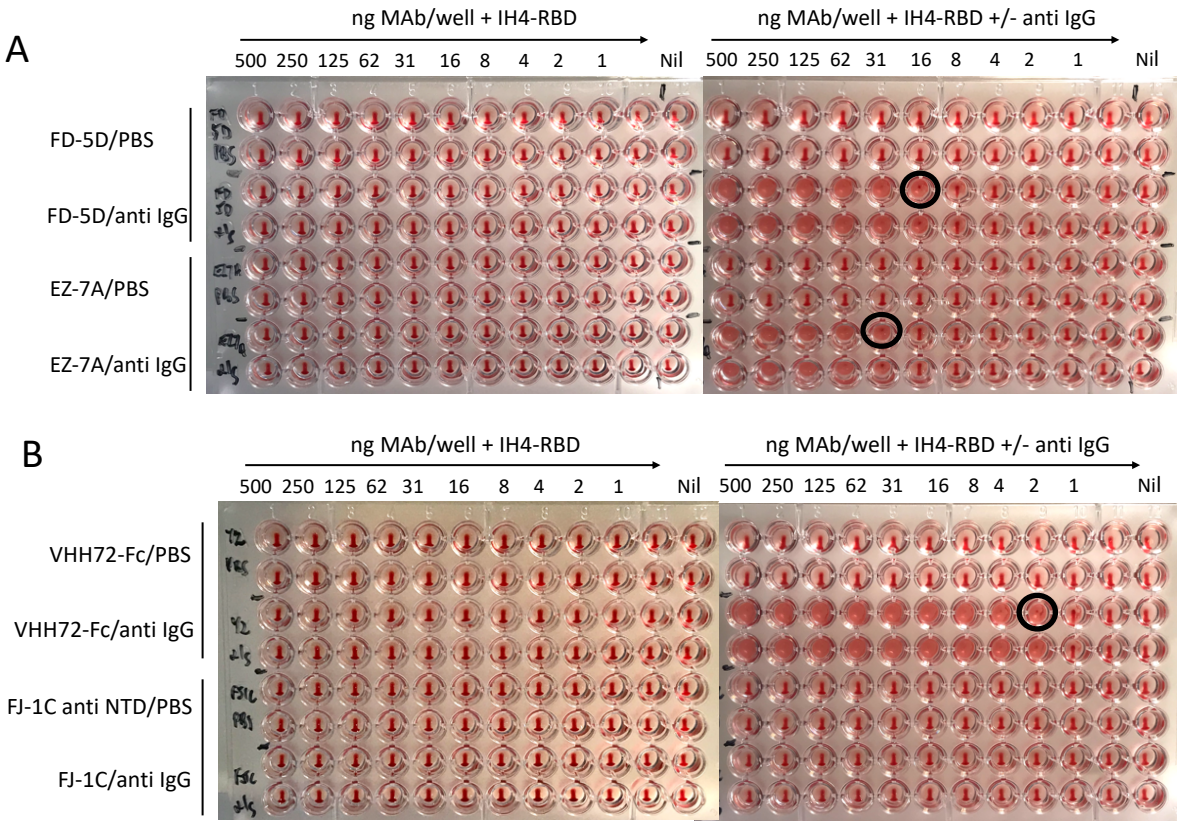
849

850 Supplementary Table 1. Fifteen human monoclonal antibodies or nanobodies with endpoint
851 titres for detection in the HA Test. One divalent nanobody VHH72-Fc and two monoclonal
852 antibodies FD-5D and EZ-7A specific for the RBD failed to agglutinate red cells with the IH4-
853 RBD reagent. Three monoclonal antibodies to other regions of the spike protein EW-8B, EW-
854 9C and FJ-1C acted as negative controls.

855

Mab or divalent Nanobody	HAT endpoint titre (ng/well)	Reference
CR3022	2	(Huo, Zhao, et al., 2020; ter Meulen et al., 2006)
EY-6A	16	(Zhou et al., 2020)
VHH-72-Fc	Negative	(Wrapp et al., 2020)
FI-4A	16	(Huang et al., 2020)
ACE2-Fc	4	(Huo, Le Bas, et al., 2020)
FI-3A	8	(Huang et al., 2020)
FI-1C	4	(Huang et al., 2020)
H11-H4-Fc	16	(Huo, Le Bas, et al., 2020)
FD-5D	Negative	(Huang et al., 2020)
FD-11A	31	(Huang et al., 2020)
FN-12A	31	(Huang et al., 2020)
FJ-10B	62	(Huang et al., 2020)
FM-7B	62	(Huang et al., 2020)
EZ-7A	Negative	(Huang et al., 2020)
S309	125	(Pinto et al., 2020)
EW-8B non-RBD anti Spike	Neg Control	(Huang et al., 2020)
EW-9C non-RBD anti Spike	Neg Control	(Huang et al., 2020)
FJ-1C anti NTD	Neg Control	(Huang et al., 2020)

856

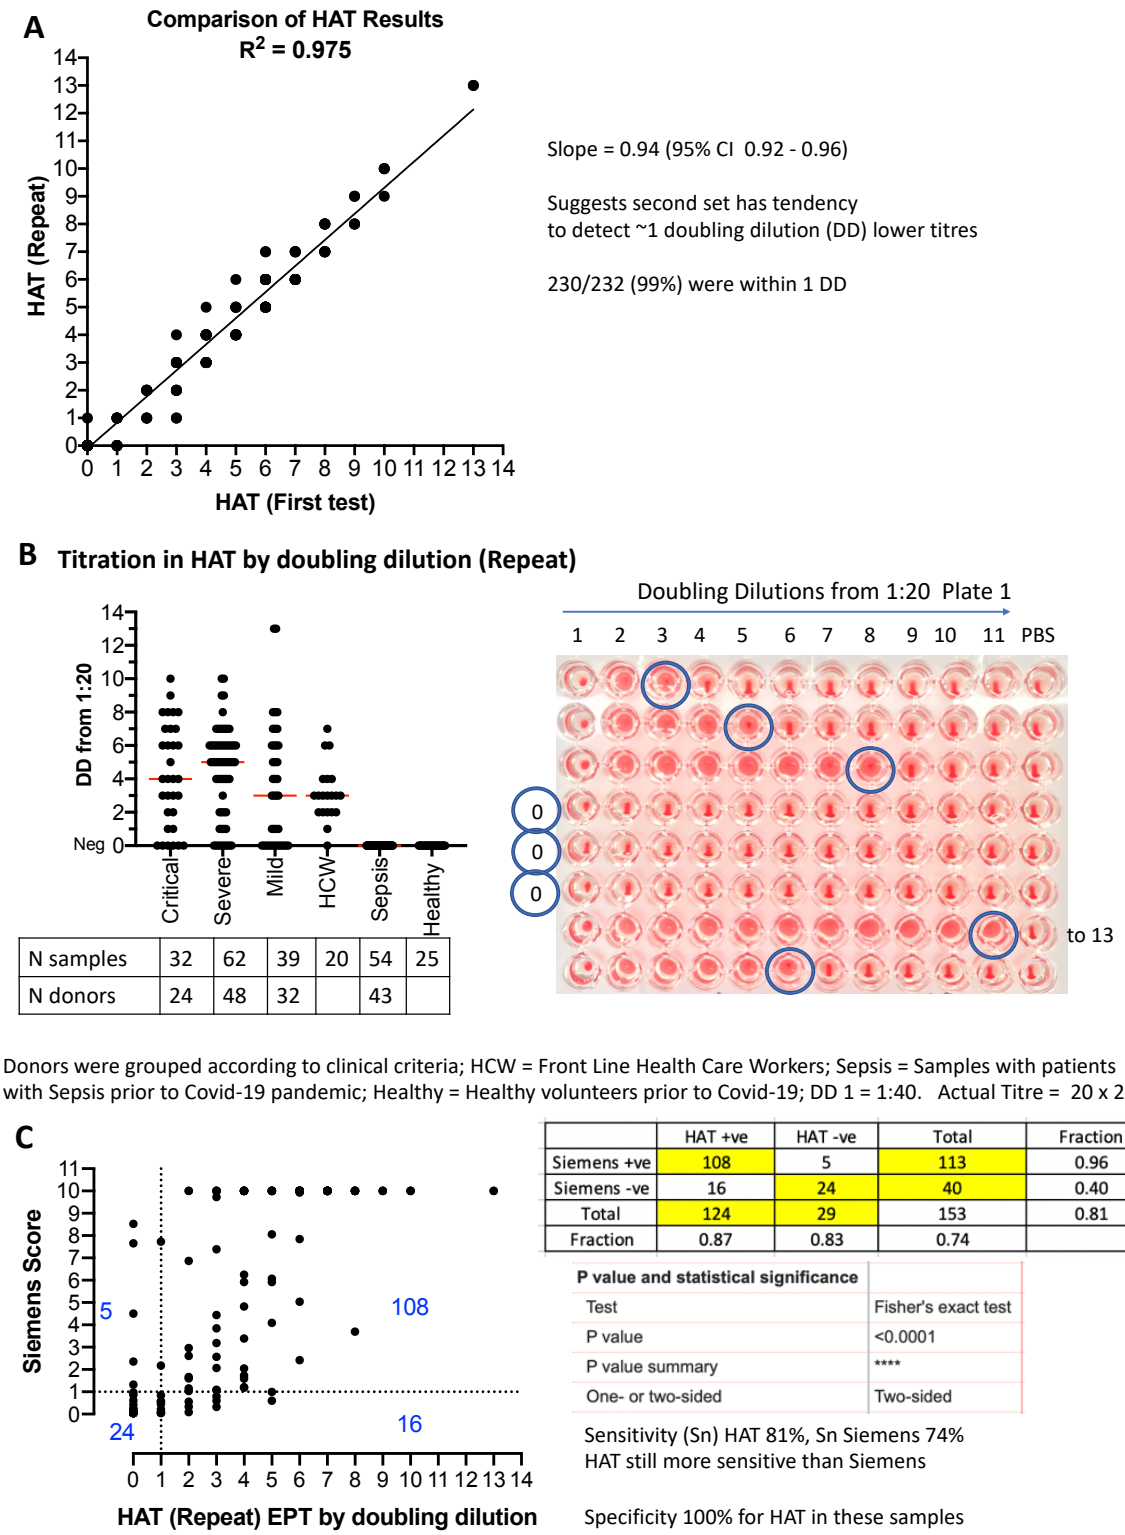


857

858 Supplementary Figure 1 A, B) Three MAbs or Nanobody-Fc reagents of 15 tested specific for
859 RBD failed to cross-link red cells but could be developed with an anti IgG reagent. Antibodies
860 were titrated from 500 ng/well to 1 ng/well in 50 µL, 1:40 red cells were added in 50 µL,
861 followed by 100 ng/well IH4-RBD in 50 µL, and incubated for 1 hour. The labelled red cells
862 were then resuspended, and either 50 µL PBS (L hand plates), or Sigma Clone GG5 anti human
863 IgG 1:100 in 50 µL (R hand plates). Red cells were allowed to settle for one hour, the plate
864 tilted for 30s and photographed.

865

866



Supplementary Figure 2

A) The 232 samples from figure 5 in the main paper were titrated a second time 34 days after the first measurement, as described for figure 4 (Methods). The values for the end point doubling dilution were compared and a correlation coefficient, and slope calculated (Prism v8).

873 B) The collection included 32 samples from 24 Critical patients, 62 samples from 48 Severe,
874 39 samples from 32 Mild, 20 single samples from health care workers (HCW), 54 samples from
875 43 patients with unrelated sepsis in the pre-Covid-19 era, 25 samples from healthy unexposed
876 controls. Median is shown.
877 C) Comparison to Siemens Result (anti RBD) with HAT Titre by Doubling Dilution for 153
878 samples from Critical, Severe, Mild and HCW PCR+ve donors. The sensitivity of the HAT in this
879 repeat was 81%, v 86% in the first test.
