Running title
HWW resistomes in Benin, Burkina Faso, and Finland

Abstract

Antimicrobial resistance (AMR) is one of the greatest global threats to human health, but substantial gaps in AMR data exist in West African countries. We explored the presence of antimicrobial resistance genes (ARGs) in the hospital wastewaters (HWW) of nine hospitals in Benin and Burkina Faso and, for comparison, four hospitals in Finland using shotgun metagenomic sequencing. The highest relative sum abundance of ARGs in HWWs was observed in Benin and the lowest in Finland. HWW resistomes resembled each other more in Benin and Burkina Faso than in Finland. Different carbapenemases were detected in varying abundances, especially in HWWs from Burkina Faso and Finland. The most widespread carbapenemase gene in the Beninese hospitals, *bla*GES, was also found in water used for handwashing. *bla*NDM was present in the HWW of one Beninese hospital and was also detected in the stools of a hospitalized patient. Mobile colistin resistance genes (*mcr*) were detected in the HWWs of all the three studied countries, with *mcr-5* as the most common variant. These and other *mcr* genes were observed in high abundance in treated wastewater released into rivers in Burkina Faso. In Benin, only little is done

to treat wastewaters, including HWWs. The results provide evidence for public health decision-makers for the dire need to increase wastewater treatment capacity, with particular attention to HWWs.

1. Introduction

The AMR crisis is a global issue with multifaceted effects on human, animal, and environmental health, and it comes with substantial economic losses (1). Resistance to almost all antibiotics, including the last resort regimen reserved to treat the most severe infections, has tended to emerge only a couple of years after introducing a new antibiotic to the global market (2, 3). Due to limitations in diagnostic testing in low-resource settings in low-income countries (LICs), broad-spectrum antibiotics are often prescribed empirically without microbiological verification of the causative pathogen or its sensitivity to different antibiotics (4). In addition, unregulated access to antimicrobials allows their wide use in these countries (5–7).

Bacterial resistance to antimicrobial compounds may be intrinsic or acquired from other bacteria or the surrounding environment via horizontal gene transfer of mobile genetic elements (MGE) (8–10). Acquired, potentially mobile ARGs are considered to have greater clinical relevance and impact the current AMR problem induced by human activity (10, 11). Class 1 integrons are strongly linked to the dissemination of clinically relevant acquired ARGs (12, 13). Although integrons are not mobile themselves, integron-carried multidrug-resistance gene cassettes can be transmitted to new hosts, for example, via plasmids (14). The gene encoding the integron integrase (*intI*), among other associated genes, is involved in the recombination of incoming genetic material into the gene cassette, and *intI1* is typically used as a marker for class 1 integrons (13, 15). Over time, quaternary ammonium compound (QAC) resistance genes, such as *qacEΔ*, have established their position in the structure of a typical class 1 integron gene cassette whose spread is induced by human activity (15, 16). It has been speculated that increasing the use of such disinfectant compounds in hospitals and community environments, especially during the COVID-19 pandemic, would further exacerbate the problem of multidrug resistance mediated by class 1 integrons (17).

The high-risk ESKAPEEc bacteria (9) (*Enterococcus faecium, Staphylococcus aureus, Klebsiella pneumoniae, Acinetobacter baumannii, Pseudomonas aeruginosa, Enterobacter* spp., *and Escherichia coli*) (18) are top priority pathogens for AMR research and the development of new antibiotics (9, 19). They can feature an impressive resistance profile in terms of both intrinsic and acquired ARGs and often exhibit multidrug-resistant phenotypes. However, investigating only bacterial isolates may result in a limited understanding of ARGs

occurring in a particular hospital. In contrast, shotgun metagenomic sequencing enables the analysis of resistomes and mobilomes (all ARGs or MGEs, respectively) as well as the microbial communities present in the studied environment (20). Hence, as opposed to PCR-based methods, there is no requirement for a priori knowledge of the resistome (20).

As a consequence of the increased prevalence of extended-spectrum beta-lactamase-producing Enterobacteriaceae (ESBL-PE), the use of broad-spectrum antibiotics has increased in clinical practice (2, 21, 22). Tracking down the spread of ESBL genes is, in many situations, no longer feasible or relevant, and attention has been directed to plasmid-mediated genes that encode carbapenemases. The carbapenemases *bla*GES, *bla*IMP, *bla*KPC, *bla*NDM, *bla*OXA-48, *bla*OXA-58, and *bla*VIM carried by plasmids have emerged and spread around the world during the past three decades (23–26).

Metronidazole is an example of an empirically widely used first-line treatment in many African countries (27). This antimicrobial drug is effective against various protozoan parasites and anaerobic bacteria (28). Although acquired resistance towards metronidazole (mediated mainly by *nim* genes) is considered to be relatively rare, an increasing trend in its emergence has been reported (28). Colistin is a last-resort antibiotic used for treating infections caused by multidrug and extensively resistant bacteria (29). The rapid emergence of mobile colistin resistance mediated by *mcr* genes threatens the efficacy of colistin in clinical use (30, 31).

Although AMR is of global concern, the crisis affects most dramatically LICs, such as those in West Africa (3, 4, 32–34). Lack of research data is a major factor hindering the development of solutions to tackle the AMR problem in these countries (4, 32, 35, 36). Despite gaps in resistance surveillance data, it is well known that the level of AMR is highest in many LICs, such as in many African countries (21, 33, 37, 38). By contrast, in Northern European countries, such as Finland, AMR occurrence is among the lowest globally, both in the community (38, 39) and healthcare settings (40).

As hospital wastewater (HWW) from healthcare facilities is considered to be at the frontline of AMR emergence and spread (41), we set out to investigate the AMR situation and the characteristics of the resistomes in nine hospitals in two West African countries, Benin and Burkina Faso, where prior data was scarce (21). For comparison, we analyzed samples from four hospitals in Finland, where the level of AMR was expected to be low (40). In this study, we applied shotgun metagenomic sequencing as it allows the analysis of the total catalog of genes present in the studied environment.

2. Results

2.1. Features of hospital wastewaters in Benin, Burkina Faso, and Finland

We analyzed hospital wastewater-associated resistomes from Benin, Burkina Faso, and Finland. On average, 31 million sequence reads per sample were analyzed. HWWs from Benin showed the highest, and from Burkina Faso the second-highest abundance of all detected ARGs normalized to bacterial 16S rRNA genes, here referred to as

the relative sum abundance of ARGs. The lowest relative sum abundance was detected in HWWs from Finland (Figure 1A, Table S3A). No significant differences were observed in the relative ARG sums among the different hospitals in each country or between the hospital sections or wards within the sampled hospitals (Table S3A). Country-wise differences for the relative abundances of class 1 integron gene (*intI1*) (Figure 1C, Table S3C) followed the trend observed for relative ARG abundances (Figure 1A). The observed high Pearson correlation of 0.80 ($p = 3.2 \times 10^{-16}$) between ARGs and intI1 genes across all 67 HWW samples indicated an association between the genes. For all MGEs, including also other than class 1 integron associated genes, a similar trend was not observed (Figure 1B, Table S3B).

The resistomes of HWWs from Benin and Burkina Faso resembled each other more than those of the Finnish HWWs (Figure 2A). The resistomes in Benin and Burkina Faso shared 384 ARGs, while Finland and Benin shared only 15 ARGs, and Finland and Burkina Faso shared 134 ARGs (Figure S4). The resistome compositions differed the most between the Beninese and Finnish HWW samples (Figure 2A). The country explained the differences in the resistomes by 29.5–33.7 % in the Benin-Finland comparison and 24.5–25.6 % in the Burkina Faso-Finland comparison (Table S1). In addition, while the ARGs found uniquely in HWWs from Burkina Faso made up approximately 14 % of all the detected ARGs in this study, the corresponding percentage for HWWs from Benin was only 2.5 % (Figure S4).

As the resistomes of West African countries and Finland were divergent, the drivers for the differences were subsequently investigated. The country explained less of the variance between taxonomical compositions than resistomes (Figure 2B, Table S1). A set of samples from a single hospital (Hospital I, Figure S3B) seemed to drive the distinct clustering seen in the microbial community in HWWs from Burkina Faso.

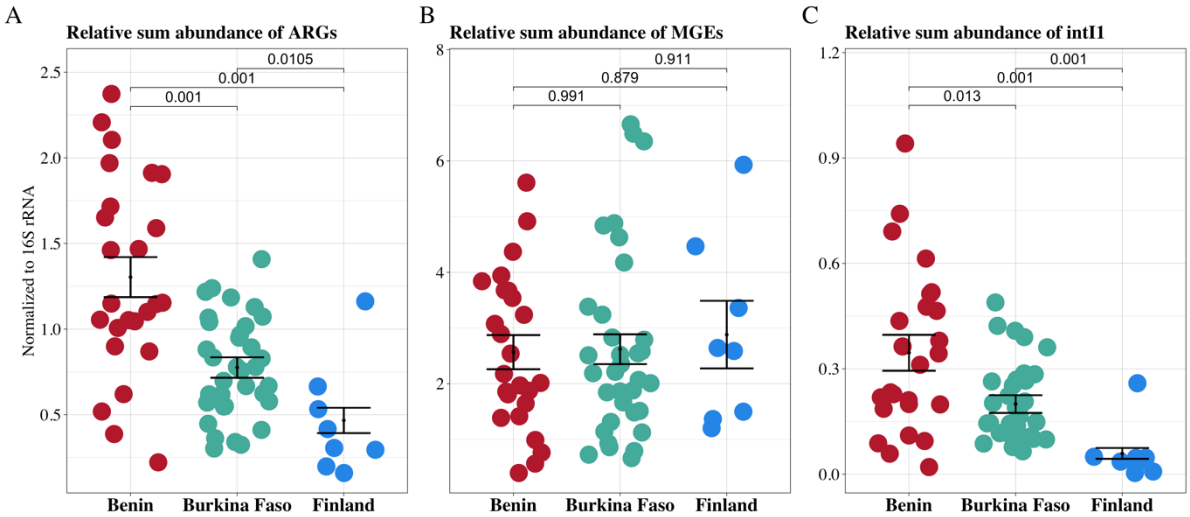

Figure 1. Relative sum abundance of ARGs, MGEs, and class 1 integrons. A generalized linear model (GLM) was fitted to 16S rRNA, and gene length normalized A) ARG B) MGE, and C) *intI1* count data to model the differences in the levels of these genes in the three countries. The vertical line shows the median in boxplots, while the lower and higher hinges denote the 25 % and 75 % quantiles, respectively. In addition, Wilcoxon signed-rank test significances are shown for pair-wise comparisons.

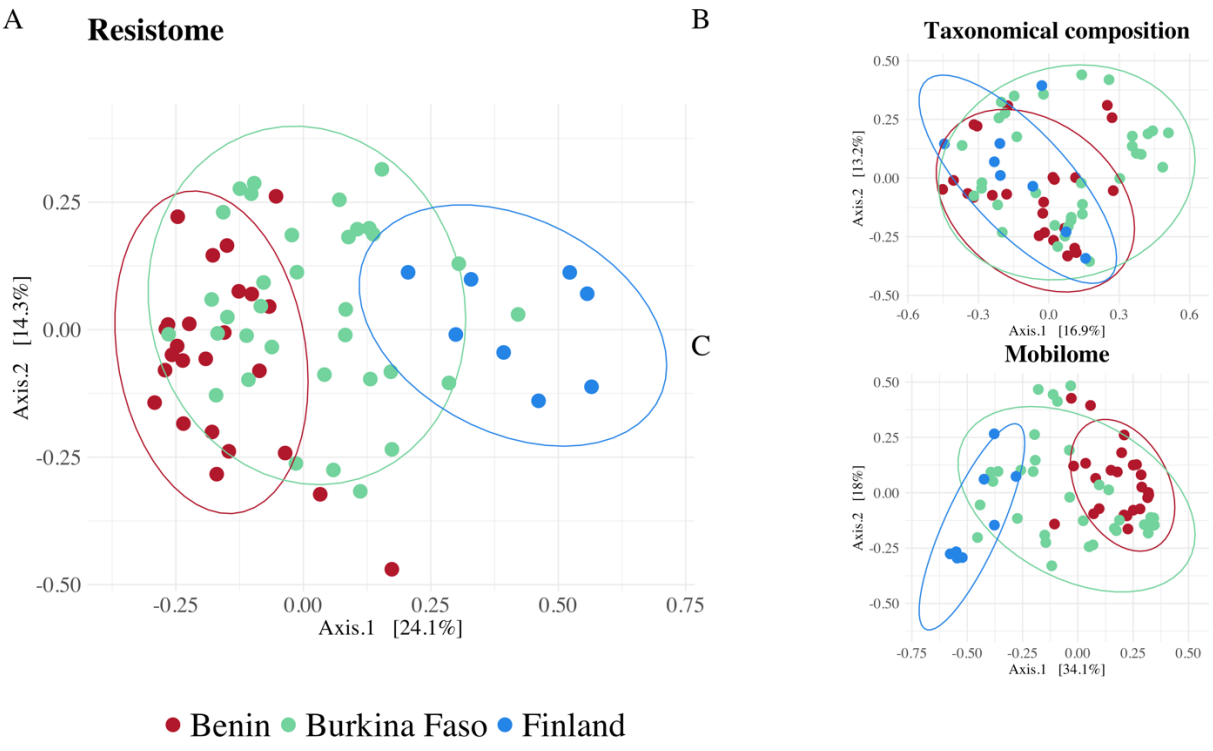

Figure 2. PCoA plots describe the ordinations based on A) resistomes, B) taxonomical compositions, and C) mobilomes in HWWs from Benin, Burkina Faso, and Finland. All 67 HWW samples were included in the plots. However, due to unequal group sizes, groups of random sample sets were applied for testing the significance of the clustering based on the country using adonis. The tests were performed in triplicate with different samples to account for variation caused by sample selection. The R^2 values are shown in Supporting Information, Table S1. Confidence ellipses represent 90 % confidence levels.

2.2. Clinically relevant taxa and associated ARGs

Taxonomical composition present in septic tanks and sumps in Benin and Burkina Faso differed from those found in hospital sewers in Finland. In Benin and Burkina Faso, the 15 most abundant genera present in HWW included *Desulfobulbus, Sulfurospirillum, Thauera,* and *Geobacter*, while in Finnish HWW, *Bifidobacterium* and *Faecalibacterium* were among the most abundant genera (Table S4). Genera known for opportunistically pathogenic species such as *Escherichia* and *Aeromonas* were detected among the 15 most abundant genera in the HWWs of all three countries (Table S4, Figure S5). *Klebsiella pneumoniae* was among the 15 most abundant species in Benin and Burkina Faso in terms of relative abundance (Table S4, Figure S5). In contrast, at the species level, *Escherichia coli, Enterococcus faecium*, and species of *Enterobacter cloacae* and *Pseudomonas aeruginosa* complexes were present but rare in all the countries. *Staphylococcus aureus* was detected exclusively in Burkinabe samples (Figure S5). Other species in the genus *Staphylococcus* were more commonly detected in HWWs from Benin, and Burkina Faso compared to Finland (Tables S5A and S6A). However, knowing the limitations of species-level taxa identification using shotgun metagenomics (42), these results must be evaluated with some caution.

There was no significant difference (adjusted p-value < 0.05) in the abundance of the genus *Acinetobacter* between the HWWs from the three countries, but the abundances of different species of *Acinetobacter* varied significantly. *A. johnsonii* and carbapenemases in the *bla*OXA-211-like group (for example, *bla*OXA-211, -212, -280, and -281) that are intrinsically carried by this species were significantly more abundant in HWWs from Finland compared to either Benin or Burkina Faso (Figure 4, Figure S5 and Tables S5A, S6A, S7, and S8). Certain species of *Acinetobacter* that are not intrinsically carbapenem-resistant, such as *A. townerii*, were detected at significantly higher relative abundances in HWWs from Benin and Burkina Faso compared to Finland (Tables S5A, and S6A).

2.3. Carbapenem resistance

The presence of seven acquired carbapenemases (*bla*GES, *bla*IMP, *bla*KPC, *bla*NDM, *bla*OXA-48, *bla*OXA-58, and *bla*VIM) was analyzed in detail due to their ability to cause complex infections with minimal treatment options when in a relevant host. One of the Finnish (hospital K) samples possessed the highest relative abundance of these carbapenemases (Figure 3A). This hospital is the University Central Hospital of the capital of Finland. In HWWs from Benin, the carbapenemase genes in the *bla*GES family seemed to dominate over other carbapenemases in all four hospitals (Figure 3A). Instead, most of the other carbapenemases were present at similar prevalence levels in HWWs from Burkina Faso and Finland (Figure 3A), in line with the observation of the lower number of different ARGs in Benin versus Burkina Faso (Figure S4).

*bla*VIM, *bla*IMP, and *bla*NDM were detected in Burkinabe and Finnish HWW samples, but they were more abundant in HWWs from Burkina Faso (Figure 3A). Among the studied acquired oxacillinases, *bla*OXA-48 was detected solely in two samples from Burkina Faso (Figure 3A). Instead, *bla*OXA-58 was present in the majority of Burkinabe and Finnish samples (Figure 3A). Interestingly, most *bla*KPC genes were exclusively detected in HWWs from Finland (Figure 3A, Table S11).

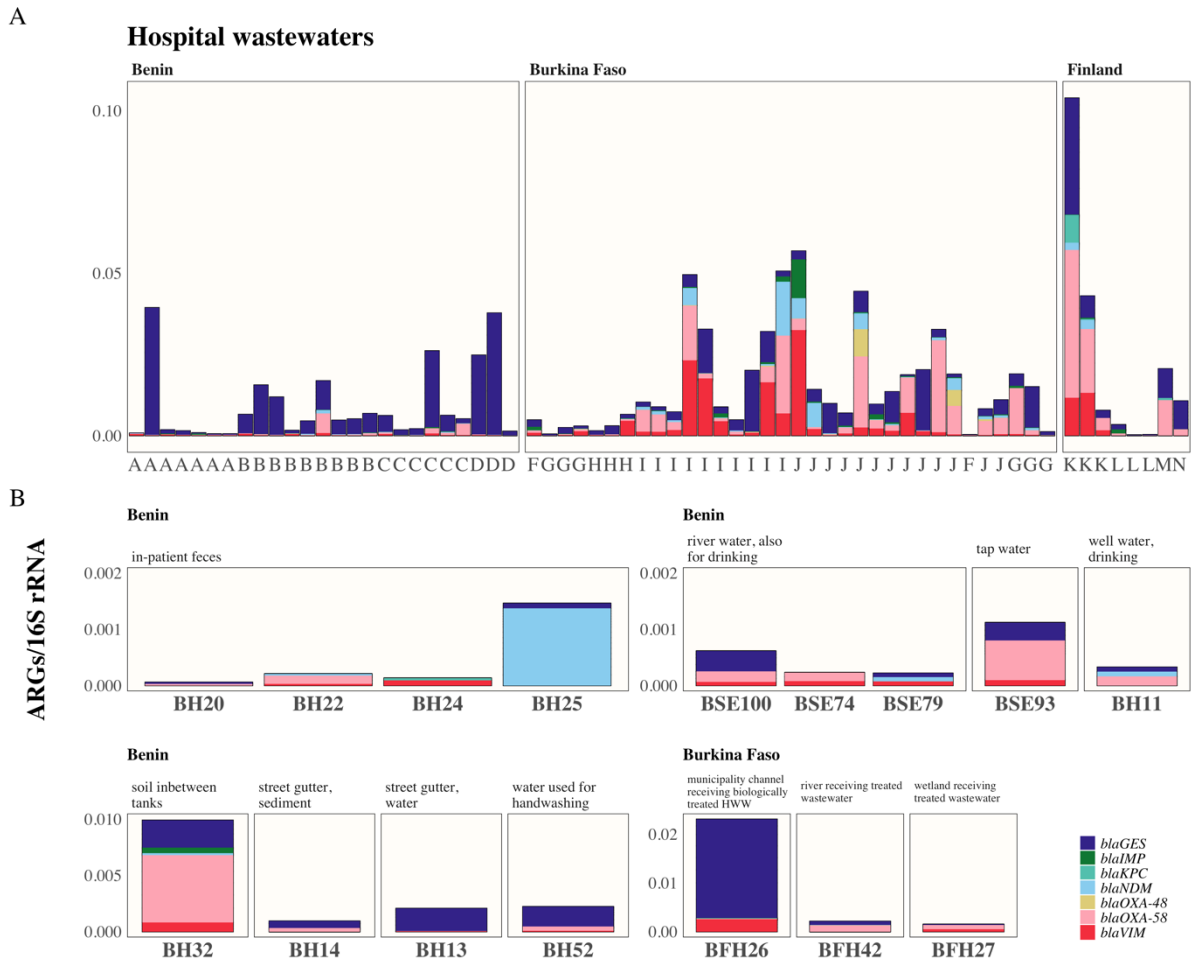

Figure 3. The abundance of carbapenemase genes in relation to 16S rRNA genes in A) HWWs from Benin, Burkina Faso, and Finland, and B) various other sample types in Benin and Burkina Faso. The hospital code (Figure 3A) and sample names (Figure 3B) are marked on the x-axis. Only the *bla*GES genes that encode carbapenemase production (*bla*GES-2, -4, -5, -6, -14, -16, -20 (25)) according to the Beta-lactamase Database (43) are shown, omitting the *bla*GES genes that encode ESBL. All screened carbapenemase gene variants are listed in Supporting Information, Table S18.

2.4. Putative role of MGEs and class 1 integrons in shaping HWW resistomes

Three methods were used to study whether the abundance of class 1 integrons could explain the differences in the relative sum abundances of ARGs between the HWWs of the three countries (as shown in Figure 1A). First, correlations between the relative abundances of the detected ARGs and the two class 1 integron-associated genes, *intI1* and *qacEΔ*, were studied (Tables S12A and S12B). These correlations were visualized for those ARGs differentially abundant in HWWs from each country in pair-wise comparisons (Figure 4). Second, contigs carrying the *intI1* gene were studied for the putative co-localization of ARG sequences (Table S13). Third, fragments carrying multiple acquired ARGs were screened visually using assembly graphs (Figure S6).

The top 20 ARGs that were more abundant in the Beninese HWWs showed stronger positive correlations with class 1 integron genes compared to the ARGs that were more abundant in Burkina Faso and Finland (Figure 4).

This suggests a stronger class I integron association of ARGs in Beninese HWWs than in the other two countries. The detection of some of these ARGs in contigs carrying several other acquired ARGs (Figure S6) or class 1 integron-associated genes (Table S13) suggests that the genes are linked to class 1 integrons. For example, the plasmid-mediated ARGs *qnrVC4* and *qnrVC5* strongly correlated with *intI1* and *qacEΔ.* The genes were located on contigs with other ARGs such as aminoglycoside ARGs and either carbapenemase (Figure S6) or ESBL genes in the *bla*GES gene family (Figure S6B). While *qnrVC4* and *qnrVC5* were more abundant in HWWs from Benin and Burkina Faso than in those from Finland, quinolone ARGs unassociated with integrons, such as *qnrB* variants, were instead more common in HWWs from Finland (Figure 4, and Tables S7, and S8).

Oxacillinases constituted half of the top 20 most abundant ARGs in HWWs from Finland (Figure 4). Most of these oxacillinases (*bla*OXA-211, -212, -334, -373, -309, -280, and -281) belong to the group of *bla*OXA-211-like carbapenemases typically intrinsically carried by certain *Acinetobacter* species and showed no significant correlation with intiI1 or *qacEΔ* (Figure 4, Tables S12A and S12B). In contrast, certain genes of oxacillinases from other *bla*OXA gene families, which were significantly more abundant in HWWs from Benin or Burkina Faso, showed significant correlation with intI1 and *qacEΔ* (Figure 4, Tables S12A and S12B) and were found in shared contigs with the *intI1* gene and other ARGs (Table S13, Figure S6C).

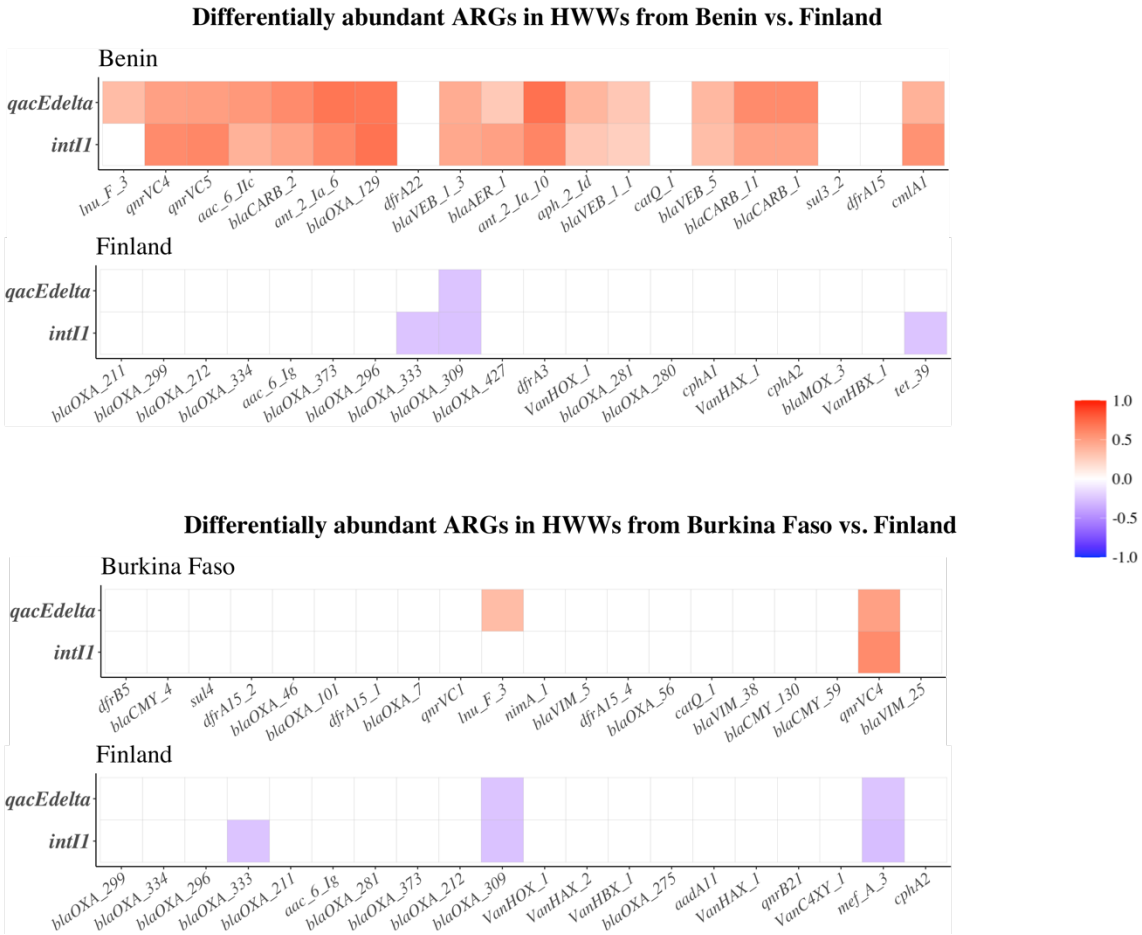

Figure 4. Differently abundant ARGs in HWWs from Benin and Burkina Faso and their putative associations with class 1 integrons. 20 significantly more abundant ARGs in HWWs of each country in pair-wise comparisons (Benin-Finland, Burkina Faso-Finland) are shown. Pearson correlations between each ARG and the genes *intI1* and *qacEΔ* associated with class 1 integrons (Supporting Information, Tables S12A, and S12B) are denoted with color-coding. The red color indicates a positive and blue negative correlation. Non-significant ($p > 0.05$) correlations are marked as blank (white) squares.

2.5. Mobile colistin resistance genes

Mobile colistin resistance genes (*mcr* genes) were observed in several HWW samples in Benin, Burkina Faso, and Finland (Table S16). Variants of *mcr-5* (*mcr-5.1* and *mcr-5.2*) were the most common as they were found in HWWs from all except one hospital (hospital F) in the three countries. We were able to confirm the location of *mcr-5* within a Tn3-like transposase element in the metagenome-assembled contigs (Figure S7, Table S14).

In addition to the HWW samples, high relative abundances of *mcr-5* genes were also detected in the immediate and more distant surroundings of the hospitals, such as in the street gutter water 100 m away from hospital B and in the soil between two HWW septic tanks in Benin (Table S15A). For hospital C, the relative abundance of *mcr-5* in a puddle surrounding the surgery room HWW septic tank was greater than the average relative sum abundance of *mcr-5* in the actual HWW septic tanks of that hospital (Figure S2D, Table S15A).

In Burkina Faso, very high relative sum abundances (2.8×10^{-2}) of *mcr-5* were observed in a municipality channel leading out from hospital I after passing through a biological treatment process (Table S15B). Furthermore, the presence of *mcr-5* was also detected in a nearby wetland where the processed wastewater is released (Table S15B). Similarly, in another Burkinabe city, *mcr-5* was found in a sample before wastewater treatment and the river receiving the water after treatment (Table S15B).

The next most prevalent *mcr* genes, namely *mcr-3, mcr-10,* and *mcr-7,* were detected in certain cases at very high relative abundances in the HWW samples (Table S16). The gene *mcr-3* was also present in the water used for handwashing at hospital C (Figure S2E, Table S15A). The gene *mcr-2* was not detected, and the lowest possible average relative sum abundance was detected for the gene *mcr-1* (Table S16).

2.6. Other than hospital wastewater samples

Other sample types within and outside the studied hospitals were investigated to obtain a more comprehensive understanding of ARG prevalence. Metronidazole resistance genes, such as *nimA* and *nimE*, were among the top 15 most abundant ARGs in the fecal samples of the four in-patients at a Beninese hospital B (Table S17). These ARGs were also significantly more abundant in HWWs from Benin, and Burkina Faso compared to Finland (Figure 4, Tables S7 and S8). *bla*NDM was detected in one of the four fecal samples (Figure 3B) and was also present in the HWWs of hospital B (Figure 3A). Other high abundance ARGs in the fecal samples included ESBL and broad-spectrum beta-lactamase genes of the *cfxA* family (Table S17).

As in the HWWs from Benin (Figure 3A), *bla*GES carbapenemases were also prevalent in other sample types from a hospital environment, such as in the water intended for handwashing (Figure S2E) for hospital C, the soil between HWW septic tanks in the yard of hospital B, and street gutter water 100 meters away from hospital B (Figure 3B). *bla*GES carbapenemase genes were also found in various waters used for drinking, including river waters in a remote countryside village (Figure 3B). However, the relative sum abundance of ARGs was low in the three rivers in central Benin (Figure 3B). We also detected *bla*NDM in well water used for drinking in Benin (Figure 3B). Albeit at low relative abundances, *bla*GES, *bla*VIM, and *bla*OXA-58-like carbapenemases were detected in natural waters receiving treated HWWs from Burkina Faso (Figure 3B). Significantly higher abundances of these ARGs were found in biologically treated wastewater before releasing into the river (Figure 3B).

3. Discussion

We characterized the bacterial community composition and resistome in 67 HWWs and 16 related samples from Benin and Burkina Faso and compared them to HWWs from Finland. This is the first study investigating hospital wastewaters in the two West African countries using a metagenomic approach. Due to the lack of systematic AMR surveillance in these countries, available data on bacterial resistance are patchy and heterogeneous (1, 4, 31, 34, 37). Thus, the magnitude of the resistance problem and the specific ARG reservoirs in many African countries are yet to be unraveled. The relative sum abundance of all ARGs detected in HWWs was the highest in Benin, yet the number of different ARGs detected there was the lowest. The differences in resistomes between the countries seemed to be only partially explained by variation in taxonomical composition, as the clustering of taxonomical composition was not as strongly correlated by country compared to clustering of resistomes. This suggests that despite differences in the HWW collection systems in the three countries (in Benin and Burkina Faso, HWW is relatively stagnant in septic tanks or sumps, while in Finland it flows in HWW drains), the microbial community compositions appear to be similar. However, of the most abundant taxa, we found many environmental bacteria in HWWs from Benin and Burkina Faso but not in Finland. This may be due to the closer contact of water with environmental surfaces in septic tanks and sumps compared to the isolated wastewater systems in Finland. Bacterial genera typically found in soil and aquatic environments (44) have also been previously described to dominate HWWs from Benin and Burkina Faso (45). In contrast, the 15 most abundant genera in Finnish HWWs included less environmental bacteria and more bacteria typical for human gut communities, such as *Bifidobacterium* (46) and *Faecalibacterium* (47). Another factor possibly explaining the differences in the dominant taxa present in the HWWs from Benin and Burkina Faso in comparison to Finland could arise from the fact that in Finland, the hospital toilet waters containing human fecal material are directed to HWWs, while for the majority of the West African HWWs studied here, this was not the case.

The ARGs that were more abundant in Benin's HWWs than in Finland appeared to be more commonly carried by class 1 integrons. They were strongly correlated with class 1 integron-associated genes (*intI1* and *qacEΔ* (15)) and, in certain cases, detected in shared contigs with these genes. Moreover, we could detect gene cassettes consisting of several different acquired ARGs linked to each other, likely referring to gene cassettes carried by

317 class 1 integrons (48). Furthermore, a higher abundance of ARGs intrinsically carried by specific species, such as
318 *bla*OXA-211 and *bla*OXA-299 genes by *A. johnsonii and A. bouvetii* (49, 50), as well as *cphA* intrinsically carried
319 by *Aeromonas* spp. (51) were distinctive features of the HWW resistomes from Finland. Intrinsic resistance is
320 often chromosomally encoded and rarely mobile or related to horizontal gene transfer (52), whereas acquired
321 resistance is typically carried by MGEs, such as class 1 integrons. As expected, no significant correlations between
322 these intrinsic *bla*OXA genes and class 1 integron-associated genes were found, supporting the observation that
323 ARGs putatively carried by class 1 integrons had a smaller impact on resistomes in HWWs from Finland compared
324 to Benin. Based on these results, we speculate that the high sum abundance of ARGs seen in HWWs from Benin
325 may, in part, be explained by the mobilome, more specifically, the prevalence of class 1 integrons. However,
326 correlation does not necessarily indicate causation, and in this study, quantitative inferences cannot be made for
327 metagenome-assembled contigs and the putative co-localization of ARGs and class 1 integron-associated genes.
328 MGEs other than class 1 integron-associated genes did not exhibit a significant correlation with ARGs. This is in
329 line with the current understanding of the role of class 1 integrons, in particular, among all MGEs in spreading
330 acquired ARGs (13).
331
332 Interestingly, the ARGs observed in HWWs from Benin were the highest in number but probably lower in clinical
333 importance compared to those in the HWWs from Burkina Faso and Finland. While the most significant
334 carbapenemase genes *bla*KPC, *bla*NDM, *bla*VIM, *bla*IMP, *bla*OXA-48, and *bla*OXA-58 were found in several
335 HWW samples from Burkina Faso and Finland at varying abundances, the abundance of many of them was low,
336 or they were not detected at all in HWWs from Benin. The *bla*GES carbapenemase genes were an exception. They
337 were the most prevalent of the seven carbapenemases in Beninese HWWs and were also found in samples
338 unrelated to hospitals.
339
340 We suspect that as *bla*GES carbapenemases are typically carried by class 1 integrons, as confirmed by previous
341 studies (53), a co-selection phenomenon (3, 54) might play a role in increasing their spread also in here. In this
342 scenario, residues of antibiotics other than carbapenems would cause the co-selection of *bla*GES. We also found
343 a high relative abundance of plasmid-mediated quinolone ARGs in the HWWs from Benin. These *qnrVC* genes
344 showed strong correlations to class 1 integron-associated genes and were in some cases found to be located in the
345 same contigs with *bla*GES-5 carbapenemase genes (Figure S6B). Hence, selection targeting quinolone ARGs
346 could co-select for carbapenem resistance encoded by the gene *bla*GES-5. Altogether our observations of ARGs
347 putatively carried by class 1 integrons are worrisome as new ARG combinations among integron gene cassettes
348 enable their selection by a broader set of antimicrobials or biocides such as quaternary ammonium compounds
349 (QACs) (15, 55, 56).
350
351 Despite the lowest relative sum abundance of ARGs detected in HWWs from Finland, some of the seven
352 carbapenemase genes of particular interest seemed to have even higher abundances in Finland than in the surveyed
353 West African countries. However, the occurrence of these ARGs was not homogenous among the Finnish samples.
354 The highest relative abundance seen in especially one sample from the University Central Hospital of the capital
355 of Finland (hospital K) was likely explained by the high patient turnover compared to other hospitals in Finland
356 and Benin and Burkina Faso studied here. Furthermore, a high relative abundance *bla*KPC was observed in only

one of the Finnish samples. Furthermore, the overall occurrence of *bla*KPC across all HWWs from Benin, Burkina Faso, and Finland studied here aligned with many local and global reports and systematic reviews (57–60), according to which *bla*KPC carbapenemases are spreading more profusely in Europe and North America than in Africa. Similarly, the relative abundance of *bla*OXA-58 was higher among Finnish than Beninese or Burkinabe HWW samples.

Disconcertingly, *bla*NDM was found in the fecal sample of an in-patient staying at a Beninese hospital. blaNDM was also detected in the wastewaters of the hospital, indicating the sensitivity of wastewater-based monitoring of bacterial resistance carried by hospital in-patients. *bla*NDM carried by *A. baumannii* has recently, in 2021, been reported in clinical settings in Benin (61).

Our observation of the high prevalence of metronidazole ARGs in Benin and Burkina Faso but not in Finland most likely reflects differences in the consumption of this drug. In LICs, diarrheal infections caused by pathogens such as *Clostridioides difficile* and other anaerobic bacteria, as well as protozoa, are common. Therefore, the consumption of metronidazole commonly used to treat these infections may be high in these countries as these drugs are being prescribed, for example, both with and without a positive diagnostic test for *C. difficile* (62). However, multidrug-resistant strains of *C. difficile* seem to already be prevalent in hospitals in certain parts of Africa as a consequence of the heavy use of antimicrobials among in-patients(62).

Compared to many HMICs such as those in Northern Europe, antimicrobial usage in agricultural (6, 7) and clinical (4) settings are less controlled – or even entirely unregulated – in many African countries. For example, while banned in many other countries, the use of colistin as a feed additive is allowed in many LICs (63), such as those in Africa (7). In contrast to previous reports on the prevalence of mobile colistin resistance globally (30) and in Africa (31, 64), *mcr-5* was the most commonly detected gene in the HWWs from our study. Instead, our observations are in line with the results obtained by using both metagenomics and qPCR (65). This discrepancy may be due to differences between the methodologies used to screen for colistin resistance. Colistin ARGs other than the best-known genes *mcr-1, -2,* and *-3* are rarely targeted when screening for mobile colistin resistance with conventional PCR (65). Our study shows that to obtain a more realistic view of mobile colistin resistance genes in Africa, screening should also be conducted for different *mcr* genes, as was recently done by Ngbede and colleagues (66).

The *mcr-5* gene detected here was embedded in a Tn3-like transposase similar to previous reports for *Salmonella enterica* (67, 68) and *Escherichia coli* (69) plasmids and the chromosome of *Cupriavidus gilardii* (67). These Tn3-like elements are flanked by inverted repeats, which enable translocation and putatively a wide host range for the *mcr-5.1* harboring element (67–69). Based on our results, the occurrences of *mcr-5* and other mobile colistin resistance genes in Benin and Burkina Faso were not restricted to HWW septic tanks. For example, at a Beninese hospital, a water puddle in the hospital yard had a higher relative abundance of *mcr* genes compared to the actual HWW septic tanks for that hospital. Furthermore, these genes were also detected in water intended for handwashing of visitors to the hospital. Thus, the transmission of these clinically critical ARGs within hospitals could be enabled via hands contaminated by this water. Similarly, Jacobs and colleagues have drawn attention to

397 the potentially inferior microbiological water quality in similar hand washing water tanks, which are very common
398 in West Africa (4).
399
400 In Burkina Faso, the relative abundance of *mcr-5* released into natural waters after wastewater treatment was high
401 (2.36×10^{-4}). For comparison, a similar relative abundance of *mcr-5* genes (3.0×10^{-4}) was reported for untreated
402 municipal wastewater in Germany (65). Although we cannot confirm the association between the *mcr-5* genes
403 detected in the natural waters and the hospital-associated wastewater in the Burkinabe hospital, our study suggests
404 the inability of the currently used wastewater treatment processes in Burkina Faso to remove colistin resistance
405 genes. Wastewater treatment systems have also earlier been described to be inadequate in Benin and Burkina Faso
406 (70). This increases the risk of the further spread of colistin and other ARGs as the inadequately treated water is
407 released into natural waters and used for various purposes by local people. Furthermore, in many African
408 countries, untreated wastewater is used for irrigation in urban agriculture, possibly enabling the dissemination of
409 ARGs to fresh produce (71, 72). The situation appears to be especially critical in Cotonou, where the hospitals
410 involved in the study did not use any kind of wastewater treatment. Groundwater in the city is extracted from the
411 shallow aquifer, which is polluted due to unauthorized waste deposits, inadequate toilets, pit latrines, and septic
412 tanks prone to leakage and hydraulic failure (73). Our study shows that untreated hospital wastewaters, which can
413 leak into groundwater and the environment, carry clinically dangerous antimicrobial-resistant bacteria and
414 resistance genes.
415
416 Taken together, based on our results from nine hospitals, we can state that clinically important ARGs are
417 circulating in West African hospitals and can spread to their surroundings. There was no significant difference in
418 the relative sum abundances of ARGs based on the hospital section or different hospitals within these countries.
419 Various carbapenem ARGs were found in HWWs from Burkina Faso and Finland, while among these *bla*GES
420 seem to dominate in the studied hospitals in Benin. Our results suggest that class 1 integron mediated co-selection
421 could play an important role in shaping the resistome in the Beninese samples. In addition to HWWs,
422 carbapenemase genes and mobile colistin resistance genes were detected in the vicinity as well as locations more
423 distant from the hospitals. Finally, there were differences between the HWW resistomes in Benin and Burkina
424 Faso concerning the relative sum abundance of ARGs and the prevalence of clinically relevant ARGs. Therefore,
425 it is important to consider the differences between African countries in AMR surveillance.
426
427 4. Material and Methods
428
429 4.1. Sample description
430
431 Hospital wastewater (HWW) samples were collected in Benin from four (hospitals A-D) and in Burkina Faso
432 from five different hospitals (hospitals F-J) in November and December of 2019. In Finland, HWW samples were
433 collected from four different hospitals (hospitals K-N) in January 2020. In Burkina Faso, the samples were mainly
434 from septic tanks or sewers in the hospital area. In Benin, none of the hospitals was connected to a sewer system,
435 and the samples were from septic tanks or sumps (unstructured wastewater wells), which were never emptied to
436 our knowledge. In most cases, the toilet water was not directed into these sumps. For comparison, some other

437 types of samples were included: samples from river waters used for drinking in a remote countryside village in
438 the community of Savalou in central Benin (n=3); river or wetland water receiving treated wastewater in Burkina
439 Faso (n=2, hospitals I and J); and fecal samples of in-patients in Benin (n=4, hospital B). In addition, the following
440 samples were analyzed; well water (hospital A), treated tap water (community of Savalou in central Benin), water
441 for handwashing (hospital C), water in a municipality channel receiving biologically treated wastewater (hospital
442 I), water and sediment from a street gutter next to the hospital (hospital B), an empty HWW septic tank (hospital
443 A), and the soil between HWW septic tanks (hospital B). The four fecal samples were obtained from patients
444 staying at hospital B with diagnoses mainly associated with musculoskeletal injuries. No clinical data concerning
445 bacterial infections were reported for these patients, and we have no information on their possible use of
446 antibiotics. Patient age varied from 24 to 50 years old, and at the time of sampling, patients had stayed in the
447 hospital for one to two months. All sample details are provided in the Supporting Information, Table S2A. Selected
448 pictures and a map indicating sample collection regions are shown in Figures S1 and S2. Letters A–N were used
449 to denote the hospitals/sampling locations.
450
451 4.2. DNA extraction and metagenomic sequencing
452
453 Water samples were collected into 1-liter bottles and transported to a laboratory on ice. They were kept at +4 °C
454 until processed within 24 hours. A volume of 50–100 ml was filtered through a 0.2 µm polycarbonate filter
455 (Whatman™, GE Healthcare Life Sciences) using a portable vacuum pump (Millivac-Mini Vacuum Pump XF54,
456 Millipore, Merck). DNA was extracted from the filters using the Qiagen DNeasy PowerWater DNA Kit for the
457 water samples and Qiagen DNeasy PowerSoil DNA Kit for the soil samples, following manufacturer instructions.
458 The concentration and quality of the extracted DNA were determined with a NanoDrop spectrophotometer.
459 Altogether 93 samples were subjected to shotgun metagenomic sequencing using Illumina Novaseq5000 with
460 Nextera XT library preparation at the Institute of Biotechnology, University of Helsinki.
461
462 4.3. Bioinformatic analyses
463
464 All samples were analyzed using an in-house Snakemake workflow (74). Briefly, the quality control steps
465 included in the workflow were performed using FastQC (75) and MultiQC (76), with adapter and low-quality
466 read removal using Cutadapt (77). Nucleotide sequence reads were mapped using Bowtie2 (78) against the
467 ResFinder database (version 3.2, downloaded on 2020-06-28) (79). The reads were sorted and filtered using
468 SAMtools (80) such that the reads mapping as pair or alone were calculated as a single count. Mobile genetic
469 elements were identified by mapping the reads against the MobileGeneticElementDatabase
470 (https://github.com/KatariinaParnanen/MobileGeneticElementDatabase, downloaded on 2020-06-28) consisting
471 of 2714 unique MGE sequences including transposases; integrons of classes 1, 2, and 3; the integron associated
472 disinfectant resistance gene *qacEΔ*; and IS and ISCR type insertion sequences (46). Class 1 integrons were studied
473 using mapping results obtained for the *intI* gene, which encodes an integron integrase (*IntI*). Taxonomic profiling
474 was performed using both Metaphlan3 (81) and Metaxa2 (82). The counts for bacterial 16S rRNA from Metaxa2
475 were used to normalize ARG and MGE counts. The lengths of the functional genes and the 16S rRNA SSU gene
476 were taken into account in the normalization.

477
478 The accuracy of the normalization method was validated by comparing two distinct methods using the 16S rRNA
479 and *rpoB* housekeeping genes. The *rpoB* counts were obtained using the translated sequence reads described above
480 as input for hmmsearch (83) against a *rpoB* specific HMM profile (pf04563) from the Pfam-A database (84). Hits
481 for forward reads (R1) were counted. The correlation between the ARGs normalized to both 16S rRNA, and *rpoB*
482 was significant ($R^2 = 0.61$, $p = 4.8 \times 10^{-8}$), and we proceeded to use 16S rRNA genes for normalization.
483
484 To study mobile colistin resistance genes (*mcr* genes) and their genetic environments for their theoretical mobility
485 potential, a subset of the samples (samples BH02, BH48, BFH19, BFH26, BFH41, FH1, and FH9) was assembled
486 using MEGAHIT (v1.2.8) (85). The minimum contig length was set to 1,000 bp. Contigs harboring mobile colistin
487 resistance genes were identified using a BLAST (86) search against *mcr* genes in the ResFinder database (n=54).
488 Similarly, contigs containing class 1 integrons were identified and screened for putative ARGs located in the same
489 contig.
490
491 Visualizing the genetic environments of contigs harboring *mcr-5.1* colistin ARGs was performed using the anvi'o
492 (v7) (87) platform tool 'anvi-interactive'. For this, single profiles were formed for the samples BH02, BH48,
493 BFH26, BFH41, and FH9 with the option '-cluster-contigs'. Then, a BLAST nr search of the contigs against the
494 ResFinder and MobileGeneticElementDatabase was performed. The resulting annotations were imported into the
495 individual sample profiles containing the contigs database and open reading frames predicted by Prodigal (v2.6.3)
496 (88) with the command 'anvi-import-functions'. The other predicted genes, sharing the same genetic environment
497 with the *mcr-5.1* gene, were identified by inspecting the resulting annotations from the BLAST nr search on the
498 web BLAST 'Graphics' view.
499
500 To simplify the presentation of the relative sum abundance results of the mobile colistin resistance genes, the *mcr*
501 genes found in ResFinder database (79) were clustered based on 90 % similarity in their sequence identity using
502 CD-HIT (v4.8.1) (89).
503
504 To visualize the co-localization of multiple ARGs with Bandage (90), the assembled contigs were converted into
505 assembly graphs using the MEGAHIT command 'megahit_toolkit contig2fastg'. The Bandage program was run
506 with a BLAST (86) query of a custom database consisting of ARGs present in the ResFinder database and the
507 integron sequence-related genes *qacEΔ* and *intI1*.
508
509 4.4. Statistical analyses
510
511 All statistical analyses described below were performed for all 67 HWW samples described in the 'Sample details'
512 section and Supporting Information Table S2B. The various wards, clinics, and other units typically had their own
513 septic tanks or sumps in the Beninese and Burkinabe hospitals. The samples were designated accordingly as
514 'surgery', 'maternity', 'pediatry', or 'other'. In addition, samples from septic tanks or sumps receiving wastewater
515 from different sources were designated as 'other'.
516

To model the relative sum abundances of ARGs and MGEs in HWWs from Benin, Burkina Faso, and Finland, a generalized linear model (GLM) with gamma distribution and logarithmic link was fitted to 16S rRNA normalized count data. The effects of the country, hospital and hospital section on the abundance of ARGs and MGEs were studied with the function 'glm' in the package MASS (v7.3-53.1) (91).

The 'ordinate' function in the Phyloseq package (v1.30.0) (92) was used for principal coordinate analysis (PCoA) of resistomes, mobilomes, and taxonomical compositions. Country-related differences in the prevalence of specific resistance genes were examined using DESeq2 (v1.26.0) (93).
The significance of the distinct clustering between the HWWs from different countries drawn using Phyloseq package (v1.30.0) (92) was tested using pair-wise adonis in the package vegan (v2.5-7) (94) with equal sample groups. For this, eight samples per country were selected randomly among the HWWs. Unique and shared ARGs were visualized with the function 'draw.triple.venn' in the package VennDiagram (v1.6.20) (95).

Pearson correlation coefficients and adjusted *p*-values for each ARG for *intI1* and *qacEΔ* genes were obtained with the function 'corr.test' in the package psych (v2.1.3) (96) and visualized using package ggcorrplot (v0.1.3) (97). The correlation tests for different normalization methods (*rpoB* and 16S rRNA) were performed similarly.

DESeq2 (v1.26.0) (93) was used to study the differentially abundant ARGs between the HWWs from the three different countries. ARGs filtered using a variance threshold of 50 were screened for significantly ($p < 0.05$) different relative abundances represented by log-2-fold changes across the HWWs of the three countries in a pair-wise manner (Benin-Finland, Burkina Faso-Finland). The DESeq2 algorithm is designed for unnormalized count data from gene expression studies. Thus, to take into account the amount of bacterial DNA in the samples (counts of detected 16S rRNA), the relative abundances were multiplied by $10^{5,}$ and a pseudo count of one was added to avoid zero values unsuitable for integer transformation. A similar analysis using DESeq2 was performed to study differentially abundant taxa found in the HWWs from Benin or Burkina Faso versus Finland. The relative abundances obtained from Metaphlan3 (81) were multiplied with the corresponding 16S rRNA counts for each sample from the Metaxa2 (82) output. Analyses for differentially abundant genera and species were conducted separately.

Statistical analyses were performed in R (v3.6.3), and the results were visualized using ggplot2 (v3.3.3) (98), pheatmap (v 1.0.12) (99), and patchwork (v1.1.0.9000) (100). Vector maps were drawn using the package rnaturalearth (v0.1.0) (101). Detailed descriptions for the bioinformatic and statistical analyses can be viewed on the project's GitHub page.

Ethical permission

The ethical permissions for the project were received from "Comité National d´Ethique pour la Recherche en Santé" under the Health Ministry in Benin and "Comité d´Ethique pour la Recherche en Santé" under the Health Ministry in Burkina Faso.

557 Supporting Information

558 The supporting information referred to within the text as Figures S1-S7 and Tables S1-S18 can be found in the
559 two separate files "Supporting_Information_1" (Figures S1-S7, Table S1) and "Supporting_Information_2"
560 (Tables S2-S18).

561

562 Acknowledgments

563 We thank the staff in all the participating hospitals for their collaboration in sampling. We also thank the laboratory
564 personnel of the URMAPha at the University of Abomey-Calavi in Benin and the Clinical Research Unit of
565 Nanoro (CRUN) in Burkina Faso for sample processing. Finally, we acknowledge CSC, IT Center for Science,
566 Finland, for providing the computational resources for the study.

567

568 Funding Sources

569 This work was supported by the Academy of Finland (Grant Numbers 346125, 318643 and 316708) and
570 University of Helsinki HiLife Grand Challenges funding.

571

572 Data availability

573 The data for this study have been deposited in the European Nucleotide Archive (ENA) at EMBL-EBI under the
574 accession number PRJEB47975 and will be public upon article publication in a peer-reviewed journal.

575

576 Code availability

577 All custom codes used for the analyses are available from https://github.com/melinamarkkanen/AMRIWA upon
578 article publication in a peer-reviewed journal.
