Abstract

Background: Spain has been disproportionately affected by the COVID-19 pandemic with the second highest death toll in the world after Italy. Here we analyzed estimates of pandemic severity and investigated how different factors shaped the severity of the COVID-19 pandemic.

Methods: We retrieved the daily cumulative numbers of laboratory-confirmed COVID-19 cases and deaths in Spain from February 20, 2020 to April 2, 2020. We used statistical methods to estimate the time-delay adjusted case fatality ratio (CFR) for 17 autonomous areas and 2 autonomous cities of Spain. We then assessed how transmission and sociodemographic variables were associated with the CFR across areas in Spain using multivariate regression analysis.

Results: We estimated the highest time-delay-adjusted CFR for Madrid (38.4%) and the average adjusted CFR in Spain at 23.9%. Our multivariate regression analysis revealed a statistically significant three predictor variables: infant mortality rate, poverty risk rate and the cumulative morbidity rate.

Conclusions:

medRxiv preprint doi: https://doi.org/10.1101/2020.04.14.20065524; this version posted April 17, 2020. Our estimates of the time-delay adjusted CFR for 12 autonomous areas/cities in Spain are significantly higher than those previously estimated for other geographic regions including China and Korea. Our results call for urgent public health interventions focusing on low socioeconomic groups to ameliorate the burden of the COVID-19 pandemic in Spain.

Key words: COVID-19, Spain, time-delay adjusted CFR, 2020

Background

Since the emergence of COVID-19 in Wuhan, China in December 2019, the novel coronavirus (SARS-CoV-2) continues to spread throughout the world, straining and overloading healthcare systems and causing substantial morbidity and mortality burden during a short time period [1]. As of April 11 2020, 1,610,909 confirmed cases including 99,690 deaths attributed to COVID-19 have been reported from 212 countries/territories/areas [1]. While the number of COVID-19 cases and deaths in China have been on a downward trend since late February 2020, the number of new reported cases soared in new hotspots in the US, Spain, Italy, France, the UK, and Iran. Thus far, Spain has reported the second highest death toll after Italy and second highest number of confirmed COVID-19 cases after the United States.

medRxiv preprint doi: https://doi.org/10.1101/2020.04.14.20065524; this version posted April 17, 2020. It is made available under a CC-BY-NC-ND 4.0 International license .

The case fatality ratio is a useful metric to assess pandemic severity, which is typically estimated as the proportion of deaths among the total number of cases attributed to the disease [2]. However, during the course of outbreak of an infectious disease outbreak such as COVID-19, real-time estimates of CFR need to be derived carefully since it is prone to ascertainment bias and right censoring [2, 3]. In particular, the disease spectrum for COVID-19 ranges from asymptomatic and mild infections to severe cases that require hospitalization and specialized supportive care. This may lead to overestimation of the CFR among ascertained cases. On the other hand, there is a delay from illness onset to death for severe cases [4], which could lead to an underestimation of the CFR [3, 5]. Therefore, statistical methods that help mitigate inherent biases in estimates of the CFR should be employed to accurately plan for medical resources such as ICU units and ventilators, which are essential resources to save the lives of critically ill patients [6-8].

Several studies have reported CFR estimates for COVID-19 [9-11]. Overall, these estimates have varied substantially across geographic regions even within the same country. For example, a recent study estimated the time-delay-adjusted CFR at 12.2% for the ground zero of the COVID-19 pandemic: the city of Wuhan [4], whereas for the most affected region in Italy (Northwest), the delay-adjusted CFR reached 23.0% [12]. The drivers behind the geographical variations in the severity of the COVID-19 pandemic are yet to be investigated, but could

medRxiv preprint doi: https://doi.org/10.1101/2020.04.14.20065524; this version posted April 17, 2020. It is made available under a CC-BY-NC-ND 4.0 International license .

provide critical information to mitigate the morbidity and mortality impact of this and future pandemics [13].

In this study we aim to estimate the severity of COVID-19 pandemic across 19 geographic areas in Spain and aim to explain how these estimates varied geographically as a function of underlying factors. For the real-time estimation of severity, we adjust for right censoring using established methods [14, 15] and report the estimates of the time-delay adjusted CFR of COVID-19 for 17 autonomous areas and 2 autonomous cities of Spain as well as for the entire Spain. We then assessed the association between different transmission and socio-demographic factors and the estimated CFRs across areas using multivariate regression analyses.

Methods

Study setting: Spain is situated on the Iberian Peninsula and is divided into 17 autonomous communities (CCAA) and 2 African autonomous cities [16]. Ceuta and Melilla are the 2 African autonomous cities whereas the 17 CCAA include: Andalucía, Aragon, Asturias, Balears, Canarias, Cantabria, Castilla-La Mancha, Castilla y Leon, Catalunya, C. Valenciana, Extremadura, Galicia, Madrid, Murcia, Navarra, Pais Vasco, La Rioja [16].

Initial cases of COVID-19 in Spain: The first case of COVID-19 in Spain was confirmed on 31st January, 2020 in La Gomera, Canary Islands in a person who was in contact with an infected person while in Germany [17]. By February 27, there were total 12 cases which increased to 45 cases in March 1 and then continued to rise rapidly throughout the country [18].

Data Sources:

The Ministry of Health of Spain releases daily report on COVID-19 cases and deaths [19]. From these reports we retrieved the daily cumulative numbers of reported laboratory-confirmed COVID-19 cases and deaths from February 20, 2020 to April 2, 2020. We then stratified the data into 20 groups that included 17 CCAA, 2 African autonomous cities and for the entire Spain.

For each CCAA we obtained data on total population size, proportion of the population older than 60 years, proportion of population at risk of poverty, and infant mortality rates from the

medRxiv preprint doi: https://doi.org/10.1101/2020.04.14.20065524; this version posted April 17, 2020. It is made available under a CC-BY-NC-ND 4.0 International license .

Statistics National Institute (Instituto Nacional de Estadística) [20]. We also obtained the data on the total area of each CCAA [21], and percentage of total consolidated expenditure on hospital and specialized services in the CCAA from the annual report issued by the national health system, 2018 [22]. Finally, we also included two transmission-related metrics: the COVID-19 initial growth rate during the 15 days of local transmission and the cumulative morbidity rate given by the cumulative number cases divided by the local population size. Additionally we obtained the shapefiles of the autonomous areas of Spain from the national geographic information system of Spain [23].

Time-delay adjusted CFR estimation

The crude CFR is defined as the number of cumulative deaths divided by the number of cumulative cases at a specific point in time. For the estimation of CFR in real time, we employed the delay from hospitalization to death, h_s, which is assumed to be given by $h_s = H(s) - H(s-1)$ for $s>0$ where H(s) is a cumulative density function of the delay from hospitalization to death and follows a gamma distribution with mean 10.1 days and SD 5.4 days, obtained from the previously published paper [4]. Let $\pi_{a,ti}$ be the time-delay adjusted case fatality ratio on reported day t_i in area a, the likelihood function of the estimate $\pi_{a,ti}$ is

medRxiv preprint doi: https://doi.org/10.1101/2020.04.14.20065524; this version posted April 17, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. It is made available under a CC-BY-NC-ND 4.0 International license .

$$L(\pi_{a,t_i}; c_{a,t}) = \prod_{t_i} \binom{\sum_{t=1}^{t_i} c_{a,t}}{D_{a,t_i}} \left(\pi_{a,t_i} \frac{\sum_{t=2}^{t_i} \sum_{s=1}^{t-1} c_{a,t-s} h_s}{\sum_{t=1}^{t_i} c_{a,t}} \right)^{D_{a,t_i}} \left(1 - \pi_{a,t_i} \frac{\sum_{t=2}^{t_i} \sum_{s=1}^{t-1} c_{a,t-s} h_s}{\sum_{t=1}^{t_i} c_{a,t}} \right)^{\sum_{t=1}^{t_i} c_{a,t} - D_{a,t_i}}$$

where $c_{a,t}$ represents the number of new cases with reported day t in area a, and $D_{a,ti}$ is the cumulative number of deaths until reported day t_i in area *a* [14, 15]. Among the cumulative cases with reported day *t* in area a, $D_{a,ti}$ have died and the remainder have survived the infection. The contribution of those who have died with biased death risk is shown in the middle parenthetical term and the contribution of survivors is presented in the right parenthetical term. We assume that $D_{a,ti}$ is the result of the binomial sampling process with probability $\pi_{a,ti}$.

We estimated model parameters using a Monte Carlo Markov Chain (MCMC) method in a Bayesian framework. Posterior distributions of the model parameters were estimated by sampling from the three Markov chains. For each chain, we drew 100,000 samples from the posterior distribution after a burn-in of 20,000 iterations. Convergence of MCMC chains were evaluated using the potential scale reduction statistic [24, 25]. Estimates and 95% credibility intervals for these estimates are based on the posterior probability distribution of each parameter and based on the samples drawn from the posterior distributions.

Multivariate regression analysis

We also explored the association between time-delay-adjusted CFR with population size, population density, proportion of population aged more than 60 years, infant mortality rate, population at risk of poverty as measured by poverty risk rate, consolidated public health expenditure on hospital and specialized services as well as with two transmission-related metrics: the cumulative morbidity rate of COVID-19 and the initial incidence growth rate across CCAAs. For this analysis, we built a multivariate linear regression model with all predictor variables to identify simplified models with significant factors linked to the variation in CFR estimates across geographic areas in Spain. We used stepwise regression method to build a final model that contained significant predictors.

All statistical analyses were conducted in R version 3.6.1 (R Foundation for Statistical Computing, Vienna, Austria).

Results:

As of April 2, a total of 117,710 cases and 10,935 deaths due to COVID-19 have been reported in Spain. Moreover, the Madrid region has reported the highest number of cases at 34,188 (29%) and deaths at 4,483 (41%) followed by Catalunya with 23460 cases (19.9%) and 2335 deaths (21.3%).

Figure 1 displays the observed and posterior estimates of crude case fatality ratio in (A) Spain (National), (B) Andalucia(AN), (C) Aragon(AR), (D) Asturias(AS), (E) Balears(IB), (F) Canarias(CN), (G) Cantabria(CB), (H) Castilla-La Mancha(CM), (I) Castilla y Leon(CL), (J) Catalunya(CT), (K) Ceuta(CE), (L) C.Valenciana(VC), (M) Extremadura(EX), (N) Galicia(GA), (O) Madrid(MD), (P) Melilla(ME), (Q) Murcia(MC), (R) Navarra(NC), (S) Pais Vasco(PV), and (T) La Rioja(RI). Day 1 corresponds to March 1st in 2020. Black dots show the crude case fatality ratio, and light and dark indicate 95% and 50% credible intervals for posterior estimates, respectively. Our model-based crude CFR fitted the observed data well in all the regions except Aragon where the model did not fit well for first 2 weeks. There was a rapid rise in crude CFR in the Madrid, Castilla-La Mancha, and Catalunya, and also for the overall Spain.

Figure 2 illustrates observed and model based posterior estimates of time-delay-adjusted CFR in the 20 areas. Black dots show crude case fatality ratios, and light and dark indicate 95% and 50% credible intervals for posterior estimates, respectively. Our posterior estimates of time-delay adjusted CFR are higher than the crude observed CFR for AR, CM, CL, CT, VC, MD, EX, PV, and at the national level. For AN, AS, CN, CB, CE, GA, ME, MC, and NC the time-delay-adjusted CFR are slightly higher than the crude CFR. Similarly, for IB the model-based estimates fit very well with the crude estimate. The graph of the time-delay

medRxiv preprint doi: https://doi.org/10.1101/2020.04.14.20065524; this version posted April 17, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. It is made available under a CC-BY-NC-ND 4.0 International license .

adjusted CFR varies considerably for different areas. For instance, as the epidemic progresses, the adjusted CFR increases slightly in CN and NC while it shows the upward trend for first two weeks and then declines very slowly as in MD. Similarly, for AR the graph shows the downward trend, probably due to misdiagnosis of cases until the first reports of deaths. Likewise, for CM the graph shows upward trend for first two weeks, followed by a relative decline and then again moves upwards and then stays stable.

A summary of the time delay adjusted case fatality ratio, range of median estimates and crude CFR of COVID-19 across different areas of Spain are presented in Table 1. The Madrid autonomous area had the highest time delay adjusted CFR of 38.4% [95% credible interval: 38.0-38.8%] followed by Castilla-La Mancha (38.2%) [95%CrI: 37.3-39.1%], Catalunya (28.9%) [95%CrI: 28.4-29.4%], and Castilla y Leon (27.9%) (95%CrI: 27.1-28.8%). The national estimate for Spain was 23.9% (95%CrI: 23.5-24.4%]. Of the 19 autonomous areas and cities of Spain, 17 had the time-delay adjusted CFR greater than 10% (Table 1, figure 3).

Autonomous areas with higher proportion of population at risk of poverty, areas with a higher infant mortality rate and areas with higher cumulative morbidity rate experienced higher CFRs. These three significant factors explained 62.2% (62.2 is multiple R-squared and adjusted R-squared is 53.5%) of variance in the pandemic severity across CCAAs ($P < 0.05$,

medRxiv preprint doi: https://doi.org/10.1101/2020.04.14.20065524; this version posted April 17, 2020. Table 2). Figure 4 demonstrates the model-adjusted CFR, infant mortality rate, cumulative morbidity rate and poverty risk rate within the map of Spain for 17 CCAAs.

Discussion

In this paper, we have estimated the time delay adjusted case fatality ratio of COVID-19 for 19 autonomous areas/cities of Spain. Our latest estimate of time-delay adjusted CFR in Spain was at 23.9%, but it varied widely across the 19 Spanish areas, with some areas exhibiting higher CFR values such as in Madrid (38.4%), and Castilla-La Mancha (38.2%) while other areas such as Melilla (3.9%), Galicia (8.2%) and Murcia (8.3%) experiencing relatively lower CFR values. We also observed a significant positive association of the time-delay adjusted CFR estimates across 17 Spanish areas with two socio-demographic factors: infant mortality rate, and poverty risk rate while cumulative morbidity rate was also positively associated with CFR. Our findings suggest the need for additional control efforts and medical resources particularly for lower socio-economic areas which have been particularly hit hard by the COVID-19 pandemic.

The adjusted CFR estimates in Spain is higher than the estimates for Wuhan (12.2%)[4], Korea (1.4%) [26] and slightly less than the estimates for Northwest Italy (31.4%)[12]. However when we compare the estimates for the most affected areas across different countries, the rate

medRxiv preprint doi: https://doi.org/10.1101/2020.04.14.20065524; this version posted April 17, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. It is made available under a CC-BY-NC-ND 4.0 International license .

in Madrid, Spain is higher than that estimated for Wuhan in China (12.2%) [4], Daegu in Korea (2.4%) [26] and Northwest, Italy (23.0%) [12]. This difference across countries and regions may be partly explained by differences in population age structure, density, other socio-demographic factors, and the scale of the pandemic in different areas. The median age in Spain (44.9 years) [27] is comparable to that of Italy (45.4 years) but higher than that for China (36.7 years) [28]. Indeed, the elderly population is at risk of severe outcomes from COVID-19 [29-31], which could partly explain the higher severity observed for Italy and Spain. Other factors that could have played a role in these differences may be related to differences in the definition of COVID-19 death, and differences in testing strategies. For example, in Korea extensive testing and rigorous contact tracing strategy were implemented [32] while testing prioritized more severe cases in Italy [31] and Spain [33].

We found a significant positive association between CFR and the infant mortality rate, the poverty risk rate and the COVID-19 cumulative morbidity rate across areas in Spain. In fact, these three variables explained more than 50% of the geographic variation in CFR. Infant mortality rate is an important indicator of an overall health of society while poverty risk rate reflects the socio-economic status of an area. In any pandemic situation like COVID-19, the poorer tend to exhibit the highest morbidity and mortality rates. For instance, lower

medRxiv preprint doi: https://doi.org/10.1101/2020.04.14.20065524; this version posted April 17, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. It is made available under a CC-BY-NC-ND 4.0 International license .

socioeconomic groups were also disproportionately affected by the 1918 influenza pandemic [34, 35].

Those with the poor economic status have higher odds of having pre-existing conditions such as cardiovascular diseases, obesity, diabetes, and cancer [36-38]. According to WHO-China-joint mission on COVID-19, the patients with no comorbid conditions had a crude CFR of 1.4% compared to very higher rates among those with preexisting conditions. For example, 13.2% for those with cardiovascular disease, 9.2% for diabetes, 8.4% for hypertension, 8.0% for chronic respiratory disease, and 7.6% for cancer [10]. Moreover, preliminary COVID-19 mortality data from the US also indicates a 2-fold age-adjusted death rate among Hispanic/Latino and 1.9-fold among Black/African American compared to Whites [39].

In our study we saw considerable variations in CFR trend across areas. For instance, as the epidemic progressed, the adjusted CFR showed a slightly upward trend in CN and NC, a rapid upward trend followed by the slow decline in MD, and a downward trend in AR. Likewise, for CM the graph showed an upward trend followed by a relative decline and then again an upward trend before staying stable. The CFR trend for the 19 autonomous areas can be helpful in the planning and implementation of health care services and prevention measures separately for

medRxiv preprint doi: https://doi.org/10.1101/2020.04.14.20065524; this version posted April 17, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. It is made available under a CC-BY-NC-ND 4.0 International license .

each of them. The downward trend in CFR as seen in some of the areas in our study suggest the improvement in epidemiologic surveillance leading to the increased capture of mild or asymptomatic cases. A higher number of mild and asymptomatic cases also indicate an increase in human-to-human transmission leading to a prolonged epidemic which can be controlled through effective social distancing measures until an effective vaccine or treatment becomes available [4].

The upward trend in CFR indicates that the temporal disease burden exceeded the capacity of healthcare facilities and the surveillance system probably missed many cases during the early phase of the epidemic [4], particularly due to a significant presence of mild and asymptomatic cases. It has been found that about 18% of the COVID-19 infections in Diamond Princess Cruise ship were asymptomatic [40]. The increasing trend in CFR could further be explained the nosocomial transmission affecting the health care workers, inpatients and their visitors [4]. In China, of 44672 confirmed COVID-19 cases, 3.8% was among the health care personnel [41]. Similarly, Wang et al. in their study suspected 41% of the patients to have human-to-human hospital associated transmission of COVID-19 [42].

Our study has some limitations. The preferential ascertainment of severe cases bias in COVID-19 may have spuriously increased our estimate of CFR [3], which is a frequent caveat

medRxiv preprint doi: https://doi.org/10.1101/2020.04.14.20065524; this version posted April 17, 2020. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. It is made available under a CC-BY-NC-ND 4.0 International license .

in this type of studies [43, 44]. Similarly, given the long infection-death time for COVID-19 which ranges between 2 to 8 weeks [29], our estimate may have been affected by delayed reporting bias [3, 5]. Similarly, in our data, the date of report reflects the date of reporting and not the date of onset of illness. Finally, we assumed infant mortality and poverty risk rate as a proxy for areas with low socio-economic groups.

Conclusion

The risk of death due to COVID-19 in Spain was estimated at 23.9%, but estimates varied substantially across 19 geographic areas. The CFR was as high as 38% in Madrid (38.4%), and Castilla-La Mancha areas and as low as 4% in Melilla and 8% in Galicia and Murcia. Of the 19 autonomous areas/cities, 16 had a time-delay-adjusted CFR greater than 10% reflecting a disproportionate severity burden of COVID-19 in Spain. Importantly, our estimate of CFR for the most affected Madrid region is higher than previous estimates for the most affected areas within China, Korea, and Italy. Our findings suggest a significant association of factors such as infant mortality rate and poverty risk rate with the increased risk of death due to COVID-19. Further studies with patient level data on mortality, and risk factors could provide a more detailed understanding of the factors shaping the risk of death related to COVID-19.

Figure legend

Fig 1: Temporal variation of risk of death caused by COVID-19 by area, Spain, March-April, 2020: crude case fatality rate (cCFR)

Observed and posterior estimates of crude case fatality ratio in (A) Spain (National), (B) Andalucia(AN),(C) Aragon(AR), (D) Asturias(AS),(E) Balears(IB),(F) Canarias(CN),(G) Cantabria(CB),(H) Castilla-La Mancha(CM),(I) Castilla y Leon(CL), (J) Catalunya(CT),(K) Ceuta(CE),(L) C.Valenciana(VC),(M) Extremadura(EX),(N) Galicia(GA),(O) Madrid(MD),(P) Melilla(ME),(Q) Murcia(MC),(R) Navarra(NC),(S) Pais Vasco(PV), and (T) La Rioja(RI). Day 1 corresponds to March 1st in 2020. Black dots shows crude case fatality ratio, and light and dark indicates 95% and 50% credible intervals for posterior estimates, respectively.

Fig 2: Temporal variation of risk of death caused by COVID-19 by area, Spain, March-April, 2020: time-delay adjusted case fatality rate

Observed and posterior estimates of time-delay adjusted case fatality ratio in in (A) Spain (National), (B) Andalucia(AN),(C) Aragon(AR), (D) Asturias(AS),(E) Balears(IB),(F) Canarias(CN),(G) Cantabria(CB),(H) Castilla-La Mancha(CM),(I) Castilla y Leon(CL), (J) Catalunya(CT),(K) Ceuta(CE),(L) C.Valenciana(VC),(M) Extremadura(EX),(N) Galicia(GA),(O) Madrid(MD),(P) Melilla(ME),(Q) Murcia(MC),(R) Navarra(NC),(S) Pais Vasco(PV), and (T) La Rioja(RI). Day 1 corresponds to March 1st in 2020. Black dots showscrude case fatality ratio, and light and dark indicates 95% and 50% credible intervals for posterior estimates, respectively.

Figure 3. Latest estimates of time-delay adjusted risk of death caused by COVID-19 by area, 2020, Spain.

Distribution of time-delay adjusted case fatality risks derived from the latest estimates (April 2, 2020) are presented. Top to bottom: (A)Spain (National), (B) Andalucia(AN), (C)Aragon(AR), (D) Asturias(AS),(E) Balears(IB), (F) Canarias(CN), (G) Cantabria(CB), (H) Castilla-La Mancha(CM), (I) Castilla y Leon(CL), (J) Catalunya(CT), (K) Ceuta(CE),(L) C.Valenciana(VC),(M) Extremadura(EX),(N) Galicia(GA),(O) Madrid(MD),(P) Melilla(ME),(Q) Murcia(MC),(R) Navarra(NC),(S) Pais Vasco(PV), and (T) La Rioja(RI)

Figure 4. Geographical variability of COVID-19 time-delay adjusted CFR, pervert risk, infant mortality rate and cumulative morbidity rate across 17 geographic areas, Spain, 2 April 2020.

Distribution of time-delay adjusted case fatality risks derived from the latest estimates (April 2, 2020) are presented. Top to b (A) time –delay adjusted case fatality rate as at April 2 2020 (B) poverty risk in 2017 (C) Infant mortality risk per 1000 birth in 2016 (D) cumulative morbidity rate as at April 2 2020.
