ABSTRACT

COVID-19 has assumed significant and lasting proportions worldwide. Following initial cases in the Western mesoregion, the State of Santa Catarina (SC), southern Brazil, was heavily affected as a whole by the pandemic in early 2021. This study aimed to evaluate the dynamics of the SARS-CoV-2 virus spreading patterns in the SC state through March 2020 to April 2021 using genomic surveillance. During this period, 23 distinct variants, including two VOCs (Beta and Gamma) were identified, among which, the Gamma and related lineages were predominant in the second pandemic wave within SC. However, a regionalization of P.1-like-II in the Western region was observed, concomitant to the increase in cases, mortality, and case fatality rate (CFR) index. This is the first evidence of the regionalization of the SARS-CoV-2 transmission and highlights the importance of tracking variants, dispersion and their impact of SARS-CoV-2 on the public health system in Brazilian states.

Keywords: SARS-CoV-2; Surveillance; Genome; SARS-CoV-2 P.1 variant.

Introduction

The COVID-19 pandemic, caused by the SARS-CoV-2 virus, is the world's most significant public health challenge of the last 100 years. This virus has infected more than 270 million people, leading to more than 5,3 million deaths worldwide by December 2021(*1*). In the same period, since the first reported case on 12/01/2019, this virus infected around 22.2 million people leading to 617 thousand deaths in Brazil and in the Southern State of Santa Catarina (SC), 1,238,056 cases and 20,101 deaths were reported (*2*).

With the virus' rapid accumulation of polymorphisms and the advance of the pandemic new variants have emerged (*3*). Thus, genomic surveillance has been essential for monitoring this disease and vital for local health agencies to have information to mitigate the effects of the pandemic and adopt strategies to increase population engagement in COVID control policies (*4*).

Until December 2021, more than 6,1 million SARS-CoV-2 genomes have been sequenced, allowing detection of several variants (*5*). Some new variants have distinctive biological characteristics from their predecessors, such as better transmission, immunological escape or distinguishing clinical symptoms (6). Some variants of SARS-CoV-2 have been defined as Variants of Interest (VOIs) or Variants of Concern (VOCs) with potential impact on public health. The main VOCs described have been: B.1.1.7/VOC 202012 (Alpha), reported in December 2020; B.1.351/501Y.V2 (Beta), December 2020; P.1/ B.1.1.248/B1.1.28 (Gamma), in January 2021; and B.1.617.2 (Delta), in May 2021 (*1*). Recently, the B.1.1.529 (Omicron) variant was reported in South Africa in November 2021 (1), evidencing that new VOC of SARS-CoV-2 are still emerging and, thus, genomic surveillance of the virus remains crucial.

In Brazil, the VOC Gamma (P.1) variant, derived of B.1.1.28, was first reported in the city of Manaus, State of Amazonas, being identified in 42% of RT-PCR positive samples collected between December 15th and 23th, 2020. Such VOC was not detected by genome surveillance using samples until November 2020 (*7*). This VOC has 1.7-2.6 times more transmissible than previous strains circulating in Brazil, showing a 1.2-1.9-fold increase in the mortality risk to adults and 5 - 8-fold for the young population (*8*), broadening the susceptible population under risk of infection and hospitalization and the needs of hospitalization and intensive care (*9*).

Among several detected mutations for VOC Gamma the E484K mutation occurs in the receptor binding domain (RBD) domain of the S protein and is believed to assist the evasion of the virus from the immune system (*10*) and, therefore, may lead to lower vaccine efficacy (*11*). Also present in the RBD domain, the N501Y mutation is associated with increased binding specificity to the host cell angiotensin-converting enzyme 2 (ACE2) receptor. Subvariants of VOC Gamma and related lineages (P.1-like-I and P.1-like-II), displaying distinct mutations, have also emerged during 2021 (*12*). Among these, P.1.1, P.1.2, and P.1-like-II have spread massively across the border States of Rio Grande do Sul (*13*) and Paraná (14) up to April 2021 and, was later concomitantly detected in SC state (*12*).

In this context, our study evaluated the dispersion of different variants of SARS-CoV-2 through March 1st, 2020 to April 30th, 2021, in the state of Santa Catarina, especially during the second wave of the pandemic (January to April 2021) when the VOC Gamma variant became predominant in Brazil.

Material and methods

87 *Studied regions and sampling*

88 The State of Santa Catarina (SC) is located in the southern region of Brazil, having
89 borders with the Paraná (North) and Rio Grande do Sul (South) states, and Argentina (West).
90 With an estimated population of 7,333,473 inhabitants, the SC state is geographically divided
91 into six mesoregions: Greater Florianópolis, Itajaí River Valley, Mountain range, Northern,
92 Southern, and Western SC (*15*).

93 Genome sequences from 203 SARS-CoV-2 positive samples collected from different
94 mesoregions of the state of Santa Catarina, Brazil through March 1st, 2020 to April 30th, 2021,
95 were generated (Figure 1A) (Supplementary Table 1). Additionally, 527 SARS-CoV-2 genome
96 sequences obtained from samples isolated in SC (Figure 1B) and 49 genome sequences from
97 samples isolated worldwide, including the original SARS-CoV-2 sequence (NC_045512.2), were
98 retrieved from the EpiCov database GISAID (*5*) and included in this study (only genome
99 sequences showing <5% ambiguous nucleotide and > 85% genome sequence coverage). This
100 study was approved by the Federal University of Santa Catarina Ethics Committee (CAAE:
101 31521920.8.0000.0121).

102 *RNA purification and sequencing*

103 The study used 203 human nasopharyngeal swab samples from SARS-CoV-2 positive
104 patients diagnosed via RT-qPCR. Inclusion criteria was a positive RT-PCR for gene E with C_t
105 values < 25. Total viral RNA was extracted using the RNA Viral Kit (QIAGEN, Hilden,
106 Germany) and the long amplicon pooled protocol was used (17). Briefly, complementary DNA
107 (cDNA) was synthesized from viral RNA using 50 µM random primers and 200 U/µL
108 Superscript IV reverse transcriptase (ThermoFisher Scientific, Waltham, MA, USA). The

109 obtained cDNA was amplified using 10 µM of 14 primer sets in individual reactions to amplify
110 different regions of the SARS-CoV-2 genome (approximately 2.5 Kb in each fragment) and 40
111 U/µL Platinum *Taq* DNA polymerase High Fidelity (Invitrogen, Waltham, MA, USA).
112 Amplicons were visualized on agarose 2% gel electrophoresis.

113 The amplicons were then pooled, purified using the AMPure XP (Beckman Coulter,
114 Brea, CA, USA) and quantified by Quant-iT Picogreen dsDNA assays (Invitrogen, Waltham,
115 MA, USA). Pools were then processed using the Illumina DNA Prep (Illumina, San Diego, CA,
116 USA), following manufacturer's protocol. Libraries were quantified using the Collibri Library
117 Quantification kit (ThermoFisher Scientific, Waltham, MA, USA), adjusted to 11.5 pM and
118 prepared for paired-end sequencing (2x 150 bp) using the MiSeq Reagent Kit V2 (300-cycles)
119 (Illumina, San Diego, CA, USA). Sequencing was performed on the Illumina MiSeq platform
120 (Illumina, San Diego, CA, USA).

121 *SARS-CoV-2 genome assembling and variant analysis*

122 The SARS-CoV-2 genome was assembled according to ARTIC protocol (*18*). Briefly,
123 raw reads were processed with Trimmomatic v. 0.39 (*19*) to trim low-quality bases and Illumina
124 adapters (Phred quality score > 25). Trimmed sequences were mapped to the human reference
125 genome (hg19 - GCF_000001405.13) to remove contaminants using BWA v. 0.7.17 (*20*). Next,
126 human-free reads were aligned to the SARS-CoV-2 reference genome (NC_045512.2) using
127 BWA with default parameters. Ivar v. 1.3 (*21*) and mpileup function from samtools v. 1.7 (*22*)
128 were used to perform variant calling and to generate genomes consensus sequences. Assembled
129 genomes were analyzed in the Nextclade (*23*) and Pangolin (*24*) platforms to classify the SARS-
130 CoV-2 variants.

131 Mutations, deletions, and insertions were used to assess the dissimilarity of the genomes
132 using the vegan R package v. 2.5.6 (*25*) with the Jaccard index method. The multidimensional
133 scaling (MDS) and the distribution of variants in SC were plotted using the ggplot2 R package v.
134 3.3.0 (*26*).

135 *Maximum-likelihood (ML) phylogenetic analysis*

136 The ML phylogeny was performed using all 779 SARS-CoV-2 genome sequences
137 (Supplementary Table 2). Sequences were aligned by MAFFT v. 7.310 (*27*) with default
138 parameters and were manually curated using AliView v.1.26 (*28*). A ML tree was constructed
139 using the alignment, with GTR+F+I as the substitution model predicted by ModelFinder (*29*),
140 1,000 bootstrap runs using UFBoot tree optimization (30) and SH-like approximate likelihood
141 ratio test (SH-aLRT) (*31*), using IQ-TREE v. 2.1.3 (*32*). ML tree was visualized and annotated
142 using the ggtree R package v. 2.0.4 (*33*).

143 *Network analysis of SC VOC Gamma and related lineages during the second wave*

144 The network analysis was performed using a total of 589 Brazilian VOC Gamma and
145 related genomes retrieved from GISAID, of which, 418 were SC SAR-CoV-2 genomes from
146 samples obtained from January 5th, 2021, to April 30th,2021, and 171 genome sequences from
147 other Brazilian states sequenced up to January 5th, 2021 (Supplementary Table 3). The ML
148 consensus tree as constructed like above, except the substitution model was GTR+F+R2. The
149 network analysis was performed using online service StrainHub with closeness centrality (*34*),
150 ML consensus tree, and corresponding metadata.

151 *Spike (S) gene sequence polymorphism and protein structure analysis*

152 For structural analysis of S protein of VOC Gamma, 57 presented full-length S protein
153 coverage of VOC Gamma sequenced in this study with 722 retrieved from GISAID (December
154 3rd, 2021), including the reference sequence (NC_045512.2) were aligned using MAFFT (*27*).
155 The mutations were represented over the 3D S protein structure PDB 6ZGG (resolution 3.8 Å).
156 The experimental structure presents a representative coverage of the N-terminal domain (NTD)
157 (Gln14 to Asp1146). The mutations were highlighted and colored according to observed
158 frequencies and built with PyMOL version 2.3.3 software (*35*).

159 **Results**

160 *Profile of SARS-CoV-2 variants in State of Santa Catarina after one year of COVID-19*
161 *pandemic*

162 A total of 23 distinct SARS-CoV-2 variants were identified among the studied genomes
163 (Figure 2A). Of these 730 complete genomes, 316 (43.2%) were classified as the VOC Gamma,
164 followed by 175 (23.9%) of the former VOI Zeta variant (P.2) in and 69 (9.4%) of the P1-like II
165 variant. Only four sequences of the VOC Alpha variant (B.1.1.7) were observed among the
166 analyzed samples.

167 The first sequenced sample was classified as a B.39 variant. Then, the B.1.1.28 and the
168 B.1.1.33 variants prevailed from May - November 2020, when the P.2 variant gradually became
169 the most prevalent. The P.2 variant peaked in December 2020 and was displaced quickly by the
170 P.1 variant. By January 2021, the P.1 variant had already taken over most of the samples in Santa
171 Catarina (Figure 2A). Until December 2020 the profile of variants is similar among the
172 mesoregions. However, in the beginning of the second wave) (January to April 2021), the
173 Western mesoregion has a distinct profile, with the P.1-like-II lineage being predominant in that

174 region. (Figure 2B). The Mountain Range was sampled only in February 2021. The VOC
175 Gamma was predominantly identified (n=10) and a single P.1-like-II was detected.

176 *VOC Gamma and related lineages in Santa Catarina.*

177 We inferred phylogenetic relationships between the SARS-CoV-2 genomes from SC and
178 the other known variants (Figure 3). Most of the SC sequences were grouped in the VOC
179 Gamma clade, which includes the P.1 and related lineages (P.1.1, P.1.2, P.1.10, P.1-like I and
180 P.1-like II). However, this parent clade generates two distinct sub-clades, one containing the
181 variant P.1-like-II and P.1-like-I, and the other clustering sequences classified as P.1 and their
182 subvariants (P.1.1, P.1.2, and P.1.10). It is noteworthy to mention that the clade formed mainly
183 by P.1-like-I and P.1-like-II variants is composed of samples from the Western SC, pointing out
184 a possible independent introduction and regionalized transmission of such variants in that region.

185 A Multidimensional scale (MDS) plot shows the clustering of the SARS-CoV-2 genomes
186 according to the mutations observed (Figure 4A). There was no clear clustering of the studied
187 SARS-CoV-2 variants according to the sampled geographic regions along the sampling period
188 (Figure 4B). However, in a separate analysis of the data from the VOC Gamma and the related
189 lineages, it was possible to observe a clustering of a set of genomes from Western SC (Figure
190 4C), mainly composed by the P.1-like-II variant (Figure 4D).

191 As the ML and the MDS analyses pointed out the evidence of genetic proximity of the
192 cluster of P.1 related lineage (P.1-like-II) in the Western SC, we compared all SC VOC Gamma
193 and related lineages sequences obtained from August 7th, 2020 to April 30th, 2021. These
194 genomes were classified based on the amino acid substitutions described in P.1-like-I (*36*) and

195 P.1-like-II (*13*) variants. Mutations that characterize each VOC Gamma related lineage profile
196 were identified and are summarized in Supplementary Figure 1.

197 The S protein of the VOC Gamma and related lineages were analyzed, higher mutation
198 frequencies (>90%) were observed as L18F, P26S, D138Y, and R190S positions of the NTD
199 region (Figure 5). The typical P.1 mutations were found in the RBD domain (K417T, E484K,
200 and N501Y), SD domain (D614G and H655Y), and overall structure (T1027I, and V1176F). In
201 20% of sequences conserved the original amino acid T20 in the NTD, being characterized as P.1-
202 like-II lineages.

203 *The rapid spread and regionalization of P.1-like-II during the second wave of COVID-19*
204 *pandemic in Santa Catarina, Brazil*

205 During the second wave of COVID-19 (January 2021 to April 2021) the VOC Gamma
206 and subvariants were the most representative SC. However, it does not present a homogeneous
207 variant distribution pattern in the mesoregions (Figure 2B). It is clear by comparative genome
208 analysis that many sequences from SC were directly connected to those in Manaus (Amazonas,
209 Brazil). Network analysis revealed that VOC Gamma and related lineage genomes had a genetic
210 proximity with genomes sequenced in the State of Amazonas (Figure 6A). The VOC Gamma
211 and related lineages from the Western SC had fewer interactions with other SC mesoregions than
212 with the State of Amazonas (Figure 6B). The city of Chapecó-SC, the major municipality of the
213 Western Santa Catarina, acted as a point of concentration and dissemination of lineages imported
214 from Manaus to other Western cities (Figure 6C).

215 Also, it was observed that in February and March 2021, 75% and 60% of the sequences
216 in the Western SC were classified as P.1-like-II, respectively (Figure 7). Furthermore, in the

same period, this mesoregion had the highest Case Fatality Rate (CFR), mortality, and the number of deaths in the state of Santa Catarina (Figure 8), which indicates that there was rapid dissemination of P.1-like-II variant in the region followed by an increase in deaths.

Taken together, these data indicate distinct introductions of VOC Gamma and related lineages in Santa Catarina, followed by a rapid dispersion of the P.1-like-II variant in the Western region of SC and a regionalization in the transmission of P.1-like-II in the Western region.

Discussion

In this study carried out between March 2020-April 2021, we sequenced 203 SARS-CoV-2 genomes from human samples collected from different regions of the SC state, representing 27.8% of the virus genomic sequences generated for this region. Assessment of SARS-CoV-2 genetic profiles (Figure 2A) allowed the identification of VOC Alpha (20I/501Y.V1/ B.1.1.7) and especially the Gamma (20J/501Y.V3/P.1) from January 2021 onwards, corresponding to the second wave of the pandemic in SC, as also observed in other Brazilian states (*37, 38*), indicating the homogeneity of the spreading pattern within Brazil at that time. However, between August 2020 - November 2020 we were able to identify the emergence of the formerly VOI P.2 (*1*) in SC, which rapidly turned to be more prevalent than the other variants circulating in the region. This variant, a descendant of B1.1.28, was originally identified in Brazil in Rio de Janeiro by July 2020, although phylogenetic analyses indicate that the variant may have arisen as early as February, 2020 (*39*). Similar to our findings in SC, P.2 was reported to have become predominant in several Brazilian states around the same period, especially in Northeastern and Southeastern Brazil, when variant P.1 turned to be more prevalent by

239 beginning 2021 (*39*), except for the State of Amazonas were P.2 variant was first detected in
240 November 2020 but was overshadowed by P.1 since its early detection and thus never became
241 the main circulating variant (*38*). After the emergence of VOC Gamma in Manaus City, State of
242 Amazonas (*7*), the first case of P.1 SC was reported in in Florianópolis City (Greater
243 Florianópolis) (hCoV-19/Brazil/SC-1326/2021) by January 8th, 2021, and the first case of VOC
244 Gamma related lineage (P.1-like-II) in Chapecó City (Western Santa Catarina) on January 22th,
245 2021, the later also reported by Gräff et al. (*12*).

246 Maximum likelihood analysis of P.1-like-II samples obtained from patients living in the
247 Western mesoregion of SC were clustered in a single, separate clade (Figure 3), while viral
248 samples from the other SC regions due to scarce P.1-like-II were mostly VOC Gamma and
249 subvariants, pointing out that introduction and initial spreading of P.1-like-II variant in SC
250 occurred via Western mesoregion (Figures 4C and 4D). Also, as highlighted in Figure 5 and
251 Supplementary Figure 1, VOC Gamma is characterized by three mutations in the Receptor
252 Binding Domain - RBD (K417T, E484K, and N501Y) that can modulate ACE2/RBD affinity,
253 increasing transmissibility or even the affinity of antibody. In addition to mutations L18F, T20N,
254 P26S, D138Y and R190S in the N-terminus (NTD), D614G and H655Y in the C-terminus of S1,
255 and T1027I and V1176F in S2 are also report to VOC Gamma (*40*). All these mutations were
256 identified in SC, however the cluster 3 and 8 contain the P.1-like-II lineage are formed by
257 sequences with the absence of T20N mutation and are composed specially by samples from
258 Western region.

259 Thus, in this study, analysis of such markers allowed identification of two main lineages
260 that are distinguished by the presence or absence of the T20N mutation in the S protein
261 (Supplementary Figure 1). This SARS-CoV-2 protein is highly glycosylated, being involved in

262 the virus evasion mechanisms of the human immune system through mutations that hinder viral
263 recognition by the immune system. Most of these glycosylation sites are located in Asp residues
264 that contains N-glycosylation sites, or Ser and Thr residues that contain O-glycosylation sites.
265 Among these, the most frequent glycosylation sites were found in N+2, where Asp is followed
266 by a Ser/Thr residues (*41)*. Remarkably, the herein reported T20N mutation at the NTD is
267 followed by a Thr (N+2) in all analyzed samples (N20X21T22) and introduces a new potential
268 O-glycosylation site within the S protein that may increase the virus capability to evade the
269 immune defenses of viral neutralization by means of antibodies, not altering the potential N-
270 glycosylation site at N17 that is also present in P.1 variants, where a Thr follows an Asp residue
271 at position 19 (N17X18T19).

272 As shown in Figure 4D, by February 2021 we identified a high frequency of the
273 subvariant P.1-like-II in samples from Western SC if comparing to the other regions of the state,
274 preceding an increase in the CFR index, mortality rate, and deaths (Figure 8A) on that
275 mesoregion. Taken together, these data indicate that P.1-like-II had high transmissibility and
276 effect on the lethality in the Western SC. Naveca et al. (*38*) showed how the second wave of
277 COVID-19 in the state of Amazonas, with a sudden rise in cases and number of deaths during
278 late 2020 and early 2021, directly correlates to the rise in Gamma frequency in the state, which
279 had reached a massive prevalence by January 2021. Faria et al. (7) demonstrated that the
280 infection by VOC Gamma is 1.1-1.8 times more severe than those previously observed by other
281 variants, considering that the results of this variant was related to higher viral loads, greater
282 transmissibility and an increase in the number of deaths.

283 The relationship between the increase in the number of cases and the appearance of
284 variants was also observed outside of Brazil, such as in India and Europe. In India, the

285 appearance of the Delta variant was observed during the second wave, correlating with the
286 consequent increase in the number of deaths. In Europe, the second wave was also marked by an
287 increase in the number of cases and deaths, which correlated with the appearance of the Alpha
288 variant (42-43).

289 However, transmission rate of SARS-CoV-2 may be affected by a variety of factors and
290 the emergence of a given variant could not be considered the unique factor to increase such rate
291 (*44*). Along several virus-inherent factors such as genetic variability, the lack or misuse of non-
292 pharmaceutical interventions (NPI), social difficulties for diagnosis or late diagnosis,
293 uncontrolled population movement (emigration, immigration, tourism) (*45*), the collapse of the
294 public health system (*46*), lower vaccination (*47*), the overtime decrease of the immune
295 protection (*46*), late or misdecisions taken by authorities (*49*), and the use of scientifically
296 unproven preventive therapies (*50 - 52*), are also important factors that might contribute to
297 increase the transmission and case fatality rates. Examples in different countries show that an
298 increase in the movement of people and low widespread adherence to the NPI was observed
299 weeks before the collapse of the public health service, and the consequent increase in the number
300 of cases and deaths (*53-54*). Indeed, the SARS-CoV-2 circulation is evidenced by the detection
301 of viral RNA copies in sewage months before being reported in people, as occurred in Santa
302 Catarina state in November 2019 (55). Thus, we cannot rule out that conjunction of both viral
303 and other biological, environmental and behavioral factors have significant influence on the
304 occurrence of SARS-CoV-2 variants presenting variable infectivity and pathological effects.
305 Such may have contributed to the differentially increased number of cases, hospitalization, and
306 deaths (CRF) in a short period of time in the Western SC as also previously observed in Manaus
307 (Amazon, Brazil) having totally distinct environmental conditions than SC.

308 With the following report of the VOC Omicron in South Africa in November 2021 (*1*),
309 this variant was rapidly detected worldwide (1) and reported in Brazil in São Paulo, late
310 November 2021, evidencing the ongoing viral adaptations and the continuing pandemic
311 spreading pattern. Considering these facts, it is of utmost importance the needs for maintenance
312 of a detailed and standardized genomic surveillance of SARS-CoV-2 variants towards precise
313 and specific identification of VOCs, avoiding erroneous epidemiological inferences and allowing
314 evaluation of vaccine efficacy across viral variants.

315 Genomic surveillance of the SARS-CoV-2 pandemic has been crucial to assess the
316 accumulation of mutations, mostly due to the enormous quantity of viral replication events, and
317 the biological outcomes of the genetic variability of each variant on the epidemiology,
318 transmissibility, infectivity, pathogenesis and vaccine efficacy and effectiveness. Since major
319 concerns over the genetic evolution of SARS-CoV-2 are related to an increased spreading
320 capability and to the escape from the immune system, genomic surveillance provides essential
321 data to prevent the current pandemic from lasting even longer.

322 **Conclusion**

323 Worldwide assessment of circulating variants of SARS-CoV-2 is crucial to predict and
324 evaluate the impact of the COVID-19 pandemic over time. In SC (Southern Brazil), an attractive
325 touristic destination, the VOC Gamma was the most prevalent variant detected among the
326 infected population. Despite such general predominance, our data suggest a primary, distinct
327 introduction, and rapid spreading of the P.1-like-II in the Western regions of SC in the initial
328 months of 2021, where it was responsible for a distinct and increased hospitalization and
329 mortality rates. This study allowed us to observe the distinct patterns of circulation of different

330 SARS-Cov-2 variants within SC regions. Thus, the continuous real–time genomic surveillance of
331 SARS-CoV-2 in Santa Catarina will offer precise epidemiological support for implementation
332 and review of policies and actions carried out by public health authorities towards control of
333 COVID-19 transmission and assessment of vaccine efficacy.

334

335 **Acknowledgments**

336 This work is dedicated to all SC citizens who suffered or passed away due to COVID-19.
337 We also are indebted to Hospital Universitário/HU/EBSERH from Federal University of Santa
338 Catarina (Florianópolis, SC, Brazil), Hospital Regional do Oeste (Chapecó, SC, Brazil) and
339 Hospital Regional Santa Terezinha (Joaçaba, SC, Brazil) for granting access to interview patients
340 and perform sample collection. This work was supported by Santa Catarina Research Foundation
341 (Fundação de Amparo à Pesquisa e Inovação of Santa Catarina, FAPESC, Santa Catarina, Brazil)
342 (grant number COV2020051000065), CAPES (Coordination for the Improvement of Higher
343 Education Personnel, Brazil), CNPq (National Council for Scientific and Technological
344 Development, Brazil) and UFSC (Federal University of Santa Catarina). We also are thankful to
345 all institutions that provide access to genome data at EpiCov (GISAID). DAP, VBF, TATP,
346 GAM, CLM, EKK and TZM were recipients of FAPESC, CAPES or CNPq scholarships.

347 **Disclaimers**

348 The opinions expressed by authors contributing to this journal do not necessarily reflect the
349 opinions of the Federal University of Santa Catarina, Brazil, or the institutions with which the
350 authors are affiliated. Funders have no role on study design, data analysis or decision to publish.

Author Bio (first author only, unless there are only 2 authors)

Dayane A. Padilha is a PhD student in Biotechnology and Biosciences at the Federal University of Santa Catarina (UFSC) and recipient of a CAPES scholarship. She works at both Applied Virology and Bioinformatics Laboratories at UFSC. Her main interest is on virus genomics applied to genomic surveillance.

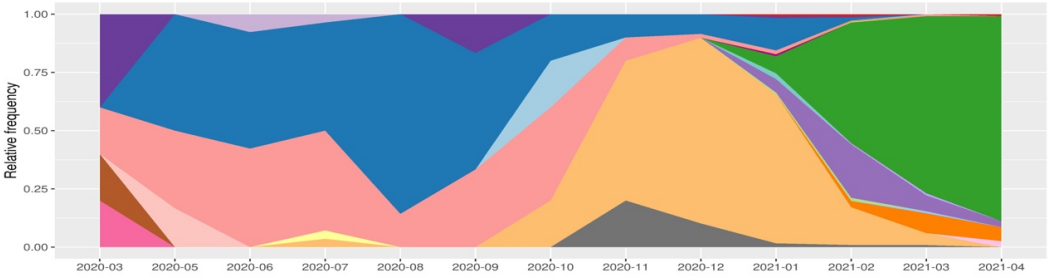
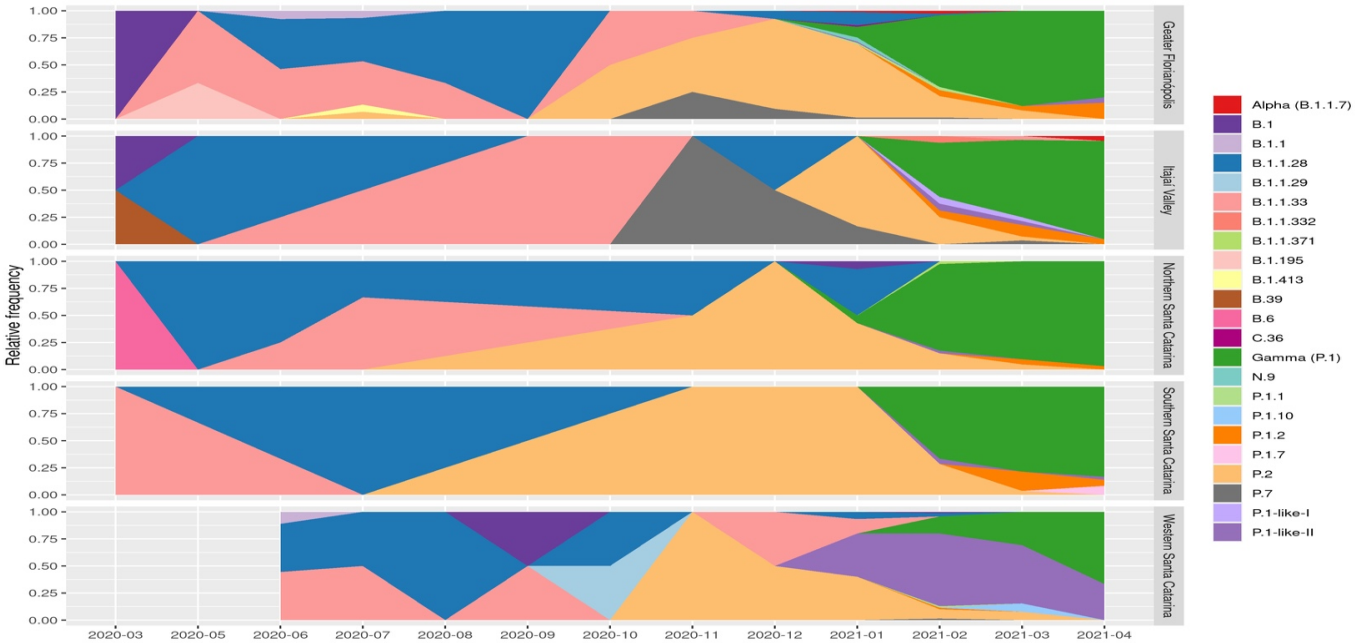
Figure 1. Distribution of sequenced SARS-CoV-2 genomes in Santa Catarina from March 1st, 2020 to April 30th 2021. **(A)** Map showing the Santa Catarina SARS-CoV-2 sequences obtained from GISAD EpiCov Database (upper map) and samples sequenced in this study (lower map). **(B)** Spatial and temporal evolution of COVID-19 cases in the state of Santa Catarina, according to the Santa Catarina Epidemiological Surveillance Directorate (*16*) during the study period. The Greater Florianópolis and the Western Santa Catarina mesoregions were the most represented because they presented the highest cases / 100,000 habitants rates between January 1st 2021 and April 30th 2021.



(A)



(B)

Figure 2. SARS-CoV-2 variants profile in the state of Santa Catarina from March 2020 to April 2021. **(A)** Analysis of the variant profile considering the whole state of Santa Catarina. **(B)** The variant profile by Santa Catarina mesoregion. From March to September 2020, the variants identified were in the highest proportion of B.1.1.28 (Blue) and B.1.1.33 (Light red). From September 2020 to January 2021, the highest proportion was of P.2 variant, followed by VOC Gamma and related lineages from February to April 2021.

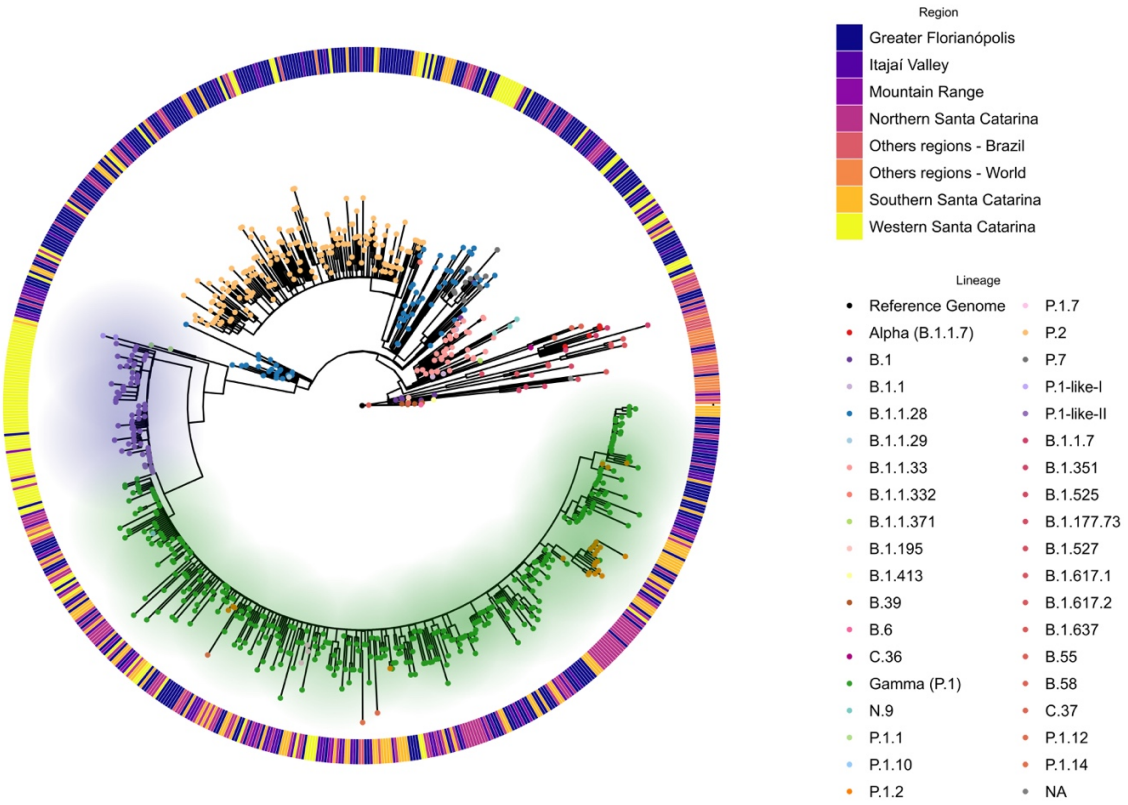


Figure 3. Phylogenomic reconstruction analysis of Santa Catarina SARS-CoV-2 sequences from March 1st, 2020 to April 30th 2021. Maximum likelihood (ML) phylogenetic tree was reconstructed using GTR+F+I substitution model, with 1000 iterations in Ultra-Fast Bootstrap mode with SH-like approximate likelihood ratio test (SH-aLRT). All 779 sequences were aligned with 49 reference sequences of distinct SARS-CoV-2 variants available in GISAID. Dots represent the variant or lineages indicated on the right-bottom legend. According to the right-up legend, the outside bars indicate the sample mesoregion of Santa Catarina or others. The green shadow indicates the VOC Gamma and related lineages (P.1.1, P1.2, P.1.10 and P.1.7) clade. Lilac shadow indicates the P.1-like-II clade.

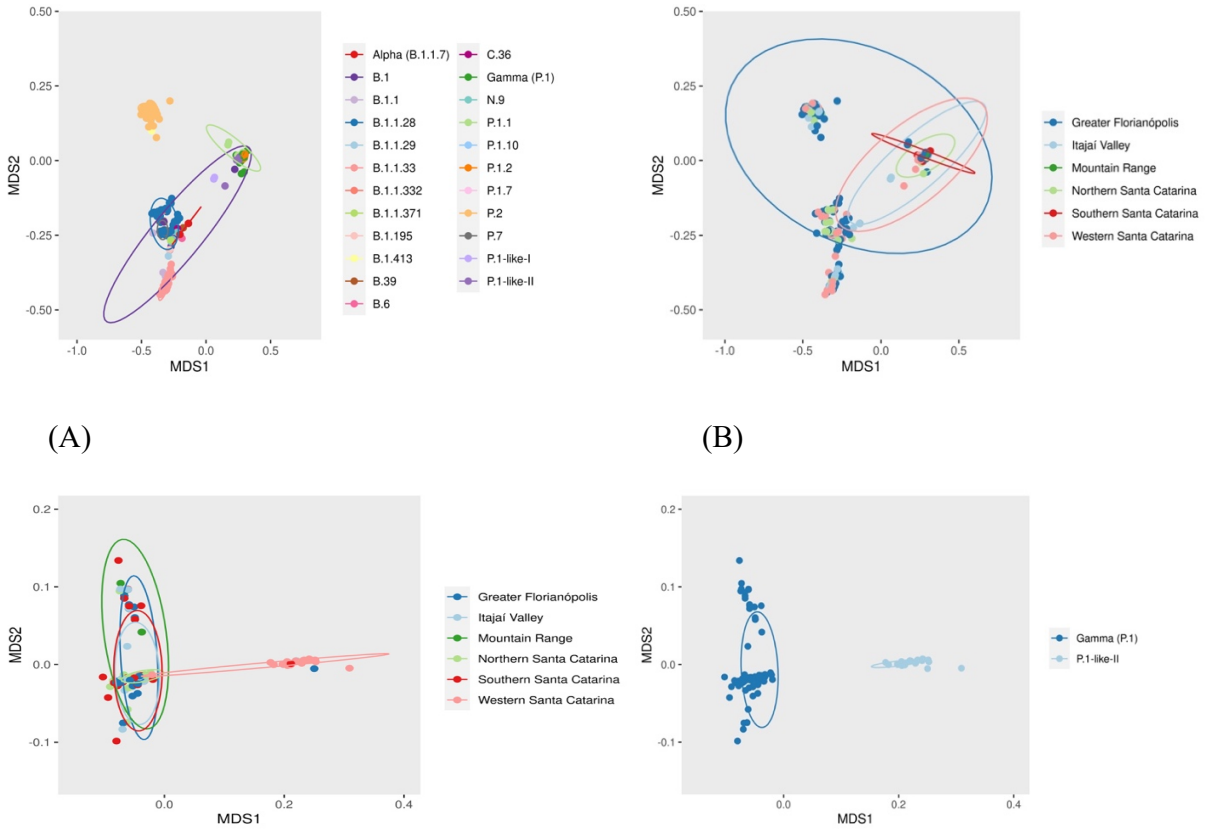

(A) (B)

(C) (D)

Figure 4. Multidimensional scale (MDS) plot of Jaccard dissimilarity matrix between genomes based on the presence and absence of mutations, deletions, and insertions labeled by **(A)** variants and **(B)** region. Only VOC Gamma and related lineages MDS analysis labeled by **(C)** region and **(D)** variant or lineages.

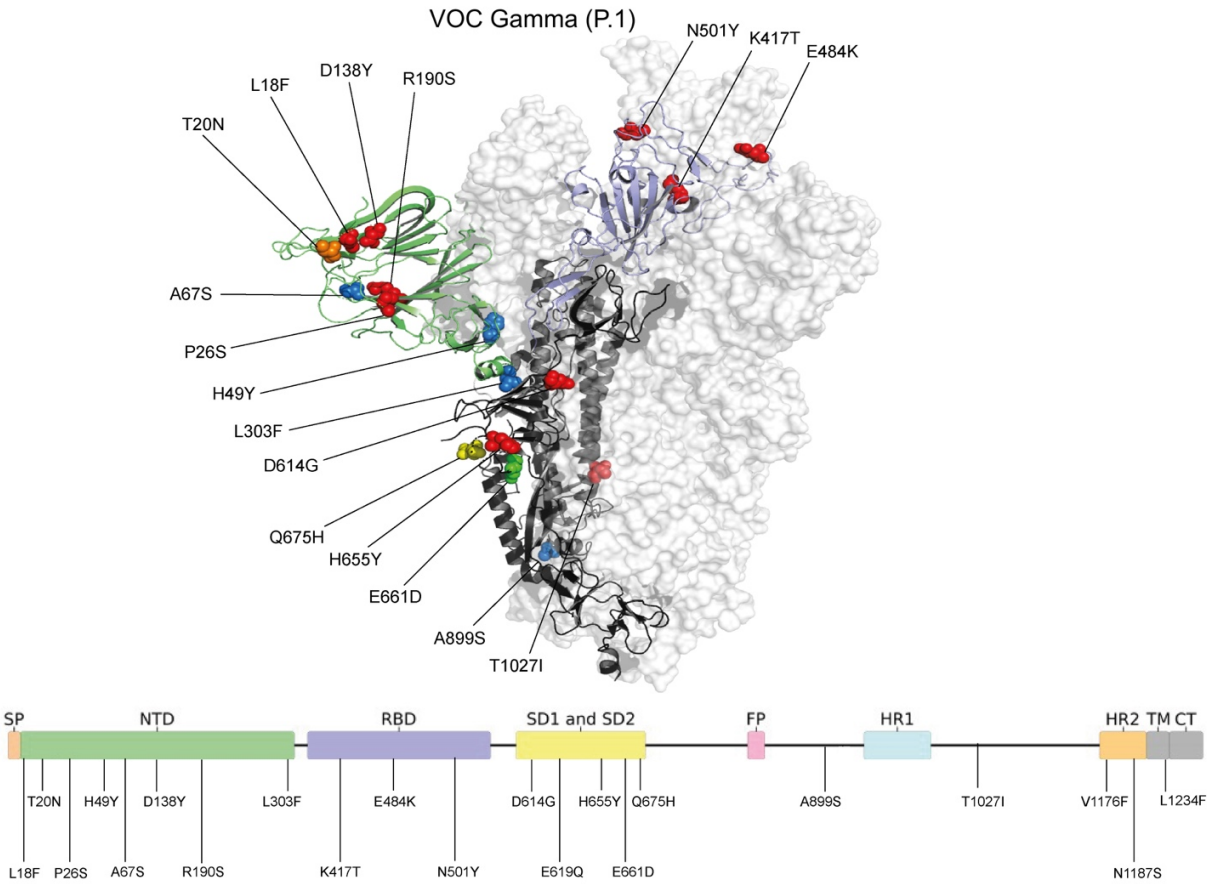

Figure 5. Overlay of VOC Gamma Spike protein mutations identified in the state of Santa Catarina during the COVID-19 pandemic. Residues involved in mutations are presented as spheres, colored from blue to red (low to high mutation frequency). The mutation sites are also indicated in the two-dimensional representation of the Spike protein, which is colored according to protein regions. The NTD domain is colored in green and the RBD domain is colored in purple. From the total of 778 analyzed sequences of the VOC Gamma variant (5' – 3'), red represents the frequency of 93.6-100%, orange the frequency of 88.8%, yellow the frequency of 3.98%, green the frequency of 1.79%, and blue the frequency of less than 1%. Image generated using PyMOL version 2.3.3 (*43*).

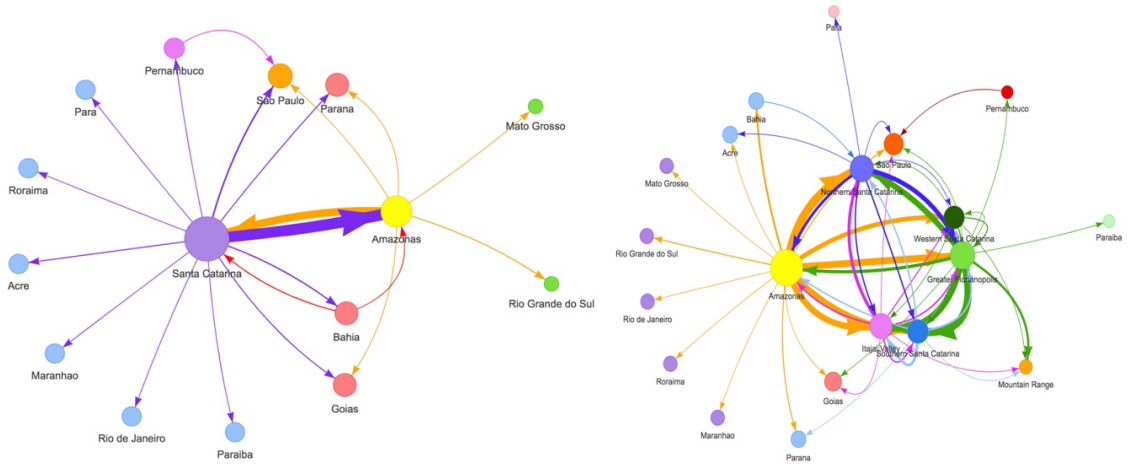
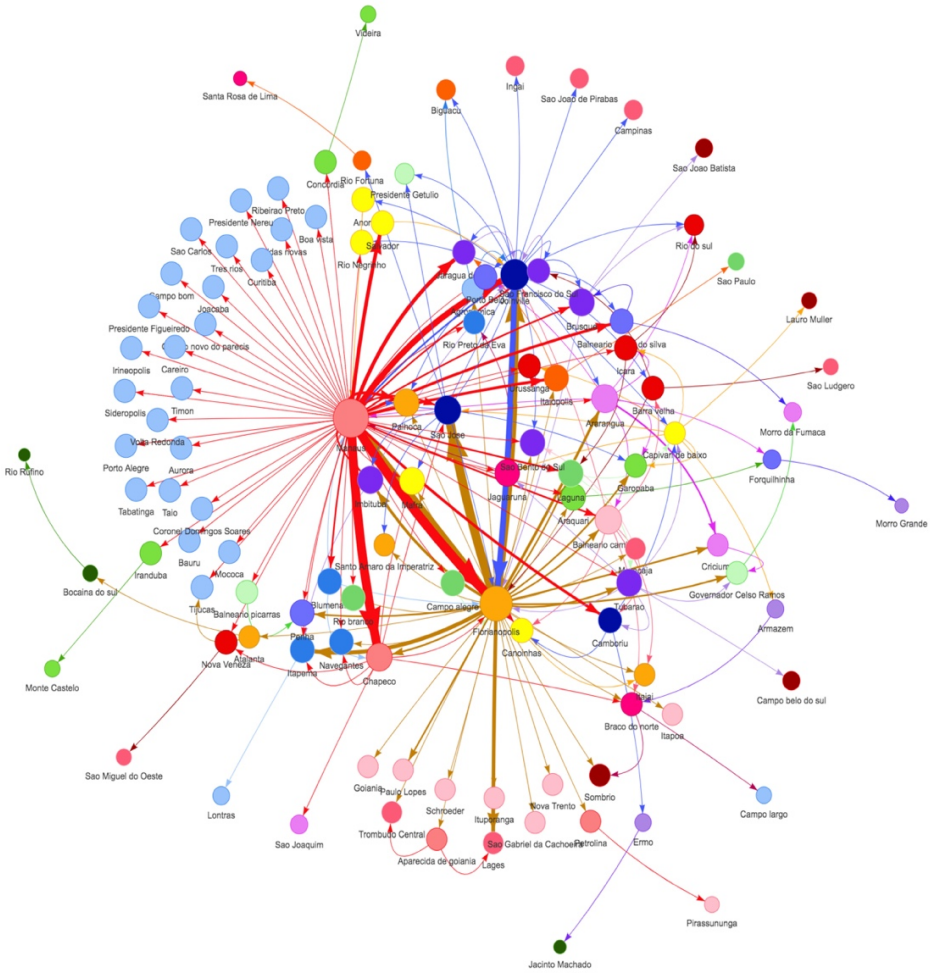


581

582 (A) (B)



583

584 (C)

585 **Figure 6.** Network analysis of VOC Gamma and related lineages sequenced in the state of Santa
586 Catarina, Brazil, from January 3rd, 2020 to April 30th 2021 with the other Brazilian states. The
587 ML analysis was performed on 13,018 Brazilian VOC Gamma related genomes obtained from
588 GISAID until April 30th, 2021 and 316 and submitted to StrainHub (*42*) analysis considering the
589 closeness parameter. The sizes of nodes are scaled by closeness metric and the arrows reflect the
590 directionality of possible transmissions between the Brazilian states **(A)**, Santa Catarina
591 mesoregions **(B)** and Santa Catarina cities **(C)**. The thickness of the lines and arrows represents
592 the frequency of putative transmissions.

593

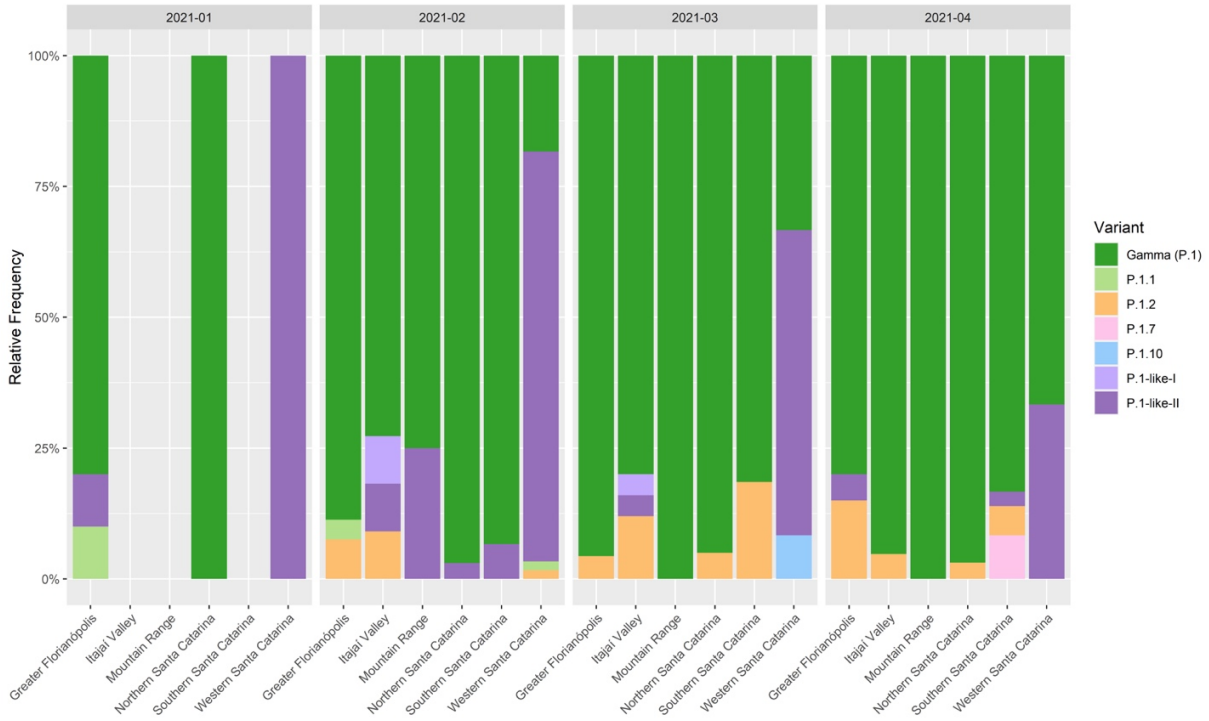


Figure 7: Relative frequencies of the SARS-CoV-2 VOC Gamma and related lineages by mesoregions of the state of Santa Catarina during the second wave of the COVID-19 pandemic, January to April 2021.

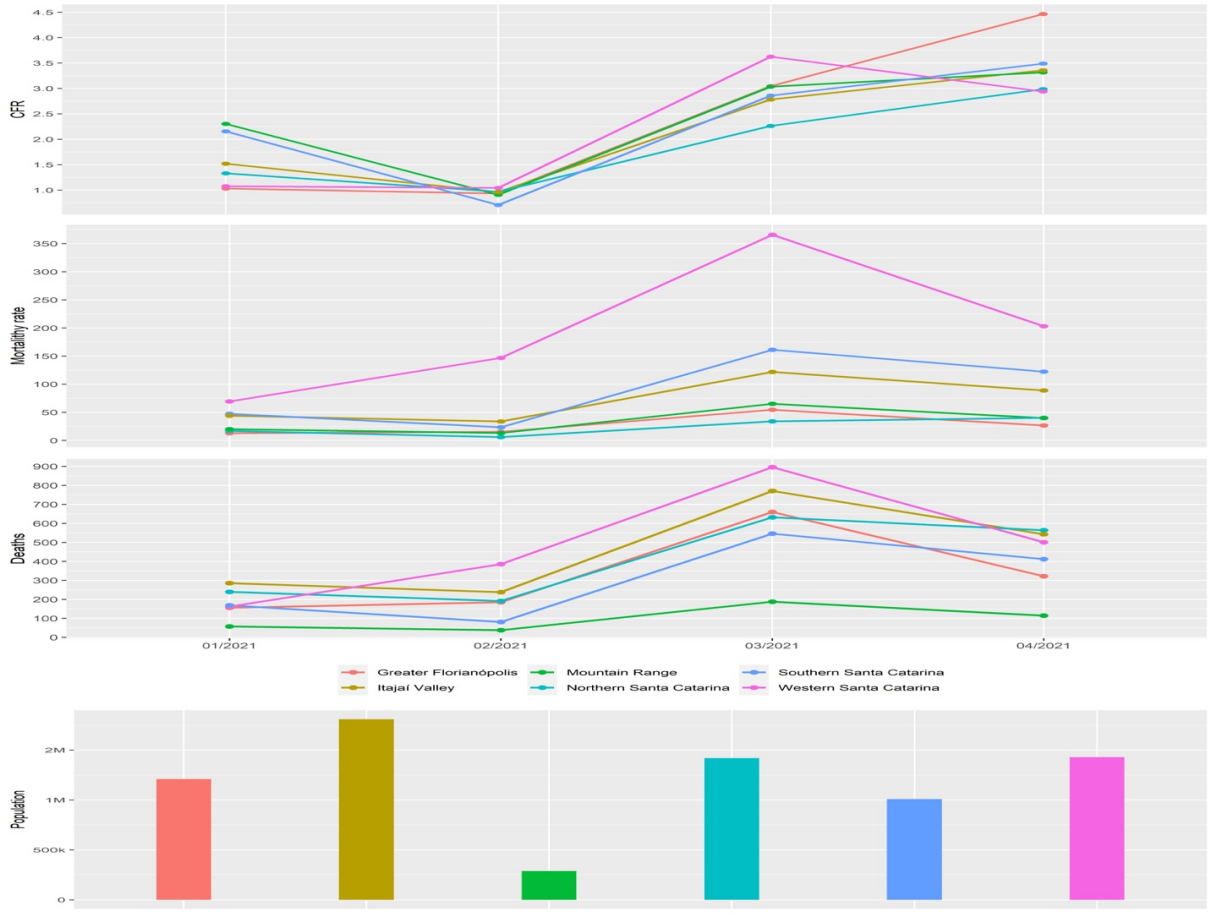

Figure 8. Epidemiological data from each mesoregion of the state of Santa Catarina during the second COVID-19 pandemic wave (January 2020 to April 2021). Case fatality rate (CFR), mortality rate, number of deaths and population size. Data source: Santa Catarina Epidemiological Surveillance Directorate (*16*).
