Abstract

Background

Acute Encephalitis Syndrome is characterised by acute onset of fever and altered sensorium followed by a rapidly worsening clinical condition and even death. The causative agents vary with season and geographic location, while the etiologies remain unknown in 68-75% of the cases. In Nepal, the cases of acute encephalitis syndrome are tested only for Japanese encephalitis, which constitutes about 15% of the cases globally. However, there could be several causative organisms, including vaccine-preventable etiologies that cause acute encephalitis, which upon identification could direct public health efforts for prevention, including expanded use of vaccines or address gaps in vaccine coverage.

Objective

This study employs metagenomic next generation sequencing in the exploration of infectious etiologies contributing to acute encephalitis syndrome in a low-and-middle-income setting.

Methods

In this study, we have investigated 90, Japanese encephalitis-negative, banked retrospective cerebrospinal fluid samples that were collected as part of a national surveillance network in 2016 and 2017. The randomisation was done to include three age groups of <5 years, 5-14 years, and >15 years. Only some metadata related to the subjects (age and gender) were known. The analysis was performed in two batches which included total nucleic acid extraction, followed by individual library preparation for DNA and RNA and sequencing on Illumina iSeq100. The generated genomic data were interpreted using CZID and confirmed with polymerase chain reaction.

Results

Human alphaherpesvirus 2 and Enterovirus B were seen in two of the ninety samples. These hits were confirmed by qPCR and seminested PCR respectively. Most of the other samples were marred by low sample quality, lack of clinical metadata, storage issues, and possible ambiguous collection procedures.

Conclusion

From this study, two documented, causative agents were revealed through metagenomic next generation sequencing. Insufficiency of clinical metadata, process controls, and absence of standard operating procedure to collect and store samples in nucleic acid protectants impeded the study and incorporated ambiguity while correlating the identified hits to infections. Therefore, there is dire need of implementing stringent collection procedures for sample collection, including proper process controls. Despite the challenging conditions, this study highlights the usefulness of mNGS to investigate diseases with unknown etiologies, such as AES, and guide the development of adequate clinical management algorithms and outbreak investigations in low-middle income settings.

Keywords: acute encephalitis syndrome, enterovirus, Human alphaherpes virus, low-middle-income country, metagenomic next generation sequencing

INTRODUCTION

Acute Encephalitis Syndrome (AES) is defined by acute onset of fever and a change in mental status (including symptoms such as confusion, disorientation, coma, or inability to talk) and/or new onset of seizures (excluding simple febrile seizures) in a person of any age at any time of year.[1] This term was coined by World Health Organization (WHO) in 2008.[1] Globally, based on various studies, the incidenceof AES has ranged from 3.5 to 7.4 per 100,000 patients-years, with a higher incidence among children.[2]

The patients suffering from AES usually present acute onset of fever and altered sensorium. This is followed by rapidly worsening clinical conditions and death.[3] The survivors can suffer from long term health issues, including neurological sequelae.[3,4] The etiologies behind AES can be grouped under infective and non-infective categories, with the infective category comprising of a broad range of organisms (bacteria, virus, parasites).[2,5] The causative agents of AES also vary with season and geographic location.[6] Research has shown that the etiologies of AES remain unknown in 68-75% of the cases, while Japanese encephalitis (JE) constitutes about 15% of the cases.[7,8,9,10] The landscape of AES, in terms of etiology, has changed in India as well, where outbreak investigations and surveillance studies have increasingly reported non-JEV etiologies.[11]

In Nepal, JE is majorly associated with mortality and morbidity among children.[12] Therefore, since 2004, the Ministry of Health and Population of Nepal, supported by the Office of Infection Prevention Division, World Health Organisation (WHO), has integrated JE surveillance with Acute Flaccid Paralysis, Neonatal Tetanus, and Measles in its National Surveillance Network.[13] Until 2011, over 23,000 AES cases were reported by the surveillance network.[14] Due to a lack of knowledge in etiology, AES cases are only tested for JE and clinical management is performed based on this result. The incidence of undiagnosed AES etiology contributes to a high rate of death and morbidity.[14] There could be several etiologies, including vaccine preventable etiologies, that cause acute encephalitis, which upon identification could direct public health efforts for prevention, including expanded use of vaccines or addressing gaps in vaccine coverage. Herpes Simplex Virus (HSV), Varicella-Zoster Virus (VSV), Enterovirus, Adenovirus, and Rubella, as well as emerging pathogens such as Nipah, Chandipura and Chikungunya have all been reported as causative viral agents of AES, while Neisseria meningitidis, Streptococcus pneumoniae, Listeria sp, and Brucella have been reported as causative bacterial agents.[2,15,16,17]

148 While molecular methods such as PCR require prior genetic information on causative agents, genomic
149 methods such as metagenomic Next Generation Sequencing (mNGS) can simultaneously identify
150 minute amounts of infections and co-infections of varying origin in a single investigation and assist in
151 the investigation of transmission of such infections.[18, 19] With the recent dramatic decrease in
152 sequencing costs, this technology provides access to genomic information in a scale that can be
153 implemented to fill gaps in routine clinical practice and address epidemiological questions. In addition
154 to identification (identifying genotypes, virulence or pathogenesis), NGS provide information
155 epidemiological investigation (comparative genomics, phylogenetic analysis).[20, 21, 22, 23]
156
157 This study, employing mNGS to explore the infective etiologies behind AES, complements a growing
158 number of studies that have used a similar approach to investigate encephalitis, including in a LMIC
159 context.[16,24,25,26] The identification of such etiologies is an important step in developing effective
160 prevention and treatment measures which in turn will reduce disability and morbidity in LMICs and
161 beyond.
162
163 **METHODOLOGY**
164 **Sample Collection and Selection**
165 The investigation included a random selection of 90 retrospective cerebrospinal fluid (CSF) samples
166 that were collected by WHO-IPD (World Health Organisation-Immunization Preventable Diseases),
167 throughout Nepal, as a part of the National AES Surveillance Network in collaboration with FWD
168 (Family Welfare Department) in 2016 and 2017. These samples had been tested for JE at NPHL
169 (National Public Health Laboratory) and stored at low but undocumented temperature. For this study,
170 only those samples that tested negative for JE were selected. A randomisation was done to include
171 three age groups of <5 years, 5-14 years, and >15 years. Only some metadata related to the subjects
172 (age and gender) were known. Each sample was provided with unique study codes to maintain privacy.
173
174 **Nucleic Acid Extraction and mNGS**
175 Total Nucleic Acid was extracted from the CSF samples using Zymo Quick-DNA/RNA™ Pathogen
176 MiniPrep (R1042).
177 The total nucleic acid samples were aliquoted into two sub samples for RNA and DNA library
178 preparation, respectively. The library preparations were done using NEB Library Prep Kit Ultra II RNA
179 for RNA (New England Biolabs, E7770S) library preparation, and NEB Library Prep Kit Ultra II FS

180 DNA for DNA library preparation (New England Biolabs, E7805S). The library preparation for the
181 first 30 samples was done in a single batch (at Chan Zuckerberg Biohub, USA) while the remaining 60
182 samples were done in three batches of 20 samples each (at Dhulikhel Hospital Kathmandu University
183 Hospital, Nepal). Negative extraction and library preparation controls were included in each batch. The
184 library preparation included 10ng of input nucleic acid, followed by fragmentation, adapter ligation,
185 cleanup (Solid Phase Reversible Immobilization beads), barcoding and amplification of library for 12-
186 16 cycles. With subsequent library preparations, quality control was done using agarose gel
187 electrophoresis and Tapestation 4200 platform from Agilent Technologies and later by qPCR using
188 Kapa Illumina Library Amplification (KK2702) and Quantitation Complete Kit (KK4923). It was made
189 sure that the length of DNA in the libraries was around 350-400bp and had concentration >1nM. In
190 RNA library preparation, ERCC (External Control Controls Consortium, 4456740) RNA Spike-in
191 controls were used.
192 The libraries that passed quality control filters were pooled and run on an Illumina iSeq100 sequencer.
193 The sequencing was performed for 2x146bp length using custom unique dual indices of 12 bp length.
194 5% PhiX was added as an internal control for sequencing. The loading concentration of pooled libraries
195 was maintained at 100-120pM.
196
197 **Data Analysis**
198 The analysis was performed on the CZ ID (formally known as IDSeq) platform developed by Chan
199 Zuckerberg Initiative and CZ Biohub. CZID accepts raw sequencing data, perform host and quality
200 filteration, followed by execution of assembly based alignment pipeline.[27]The samples are analysed
201 based on number of reads per million (Number of reads aligning to the taxon in the NCBI NR/NT
202 database, per million reads sequenced), reads (Number of reads aligning to the taxon in the NCBI
203 NT/NR database), contig number (Number of assembled contigs aligning to the taxon in the NCBI
204 NT/NR database), id% and z-score. The samples were also visualized using a rpm heatmap where
205 samples and controls are cross-matched against each other. Respective background models were
206 created, from negative extraction and library preparation control, for RNA and DNA Libraries.
207
208 **PCR Confirmation**
209 Human alphaherpes virus confirmation was done by qPCR (KAPA HiFi HotStart Ready Mix) using
210 two primer sets: established primers (FP: 5'TGCAGTTTACGTATAACCACATACAGC 3' and RP: 5'
211 AGCTGCGGGCCTCGTT 3') and self-designed primers (FP: 5' GACTCAAACACGTGCACCAC

212 and RP: 5' CCATCGCGTACAGCCTACAT 3').[28] The primer sets were designed using NCBI primer
213 blast and Gene Script, then checked with Beacon Designer Free and Snap Gene Viewer.
214 Similarly, for confirmation of Enterovirus, modified protocol with established primers from
215 Enterovirus Surveillance Guidelines were used to perform semi-nested Polymerase Chain Reaction
216 (snPCR).[29] The protocol followed visualisation of the bands, for confimration, in agarose (1.5%) gel
217 electrophoresis.
218
219 **Ethics**
220 This study was ethically cleared from Nepal Health Research Council (NHRC) under id: 903 – 2019.
221
222 **RESULTS**
223 **Subject Metadata**
224 The samples selected for this study were banked, retrospective CSF samples collected in 2016 and
225 2017 with limited metadata such as age and gender. Out of the 90 subjects, 31 (34.4%) were female
226 while the age distribution has been presented below:
227 **Table 1: Age Distribution between subjects with AES**

SN	Age Group	Number
1	<5 years	23
2	5-14 years	14
3	>15 years	53

228 The median age of the subjects infected with AES was 20 years (IQR: 4-79 years)
229
230 **Sample collection**
231 The samples were collected in glass bottles without any preservative and transported to NPHL where
232 they, first, had been tested for JE and subsequently stored at undocumented but low temperature. As
233 these samples were collected in 2016 and 2017 and banked, negative controls were not available during
234 collection and transportation.
235
236 **Nucleic Acid Extraction and mNGS**
237 The extracted nucleic acid had a concentration ranging from too low to detect to 222 ng/ul. As the
238 analysis was done in two sets. Each set was processed for DNA and RNA Library Preparation and has

been presented accordingly. Out of 90 samples, only two samples showed confirmed hits from Enterovirus B and Human alphaherpesvirus 2, respectively.

mNGS of RNA Libraries

The results from RNA libraries showed some distinct organisms hit in CZID, and also provided a broad picture of the landscape of taxa across the samples. The following are heatmaps generated from through RNA library preparation.

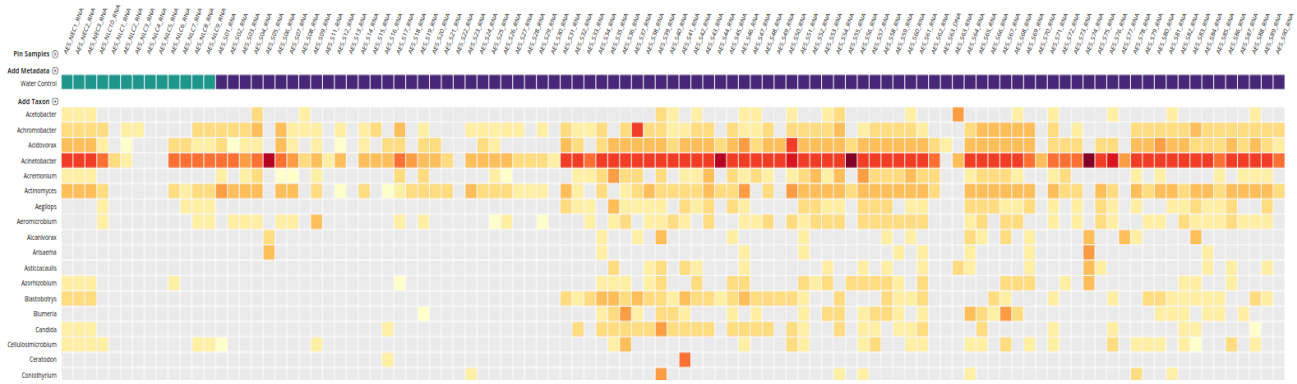

Figure 1: Heatmap depicting top hits from sequencing of RNA library for S01 to S90. The organisms (at the genus level) that were seen in the samples are shown on the left. The names of the samples are on the top of the heat map. The samples marked by green are water controls during extraction (NEC) and library preparation (NLC). The heatmap was generated using the threshold of NT rPM (nucleotide reads per million) >=10 and NT L (alignment length in basepairs: length of the aligned sequence)>=50

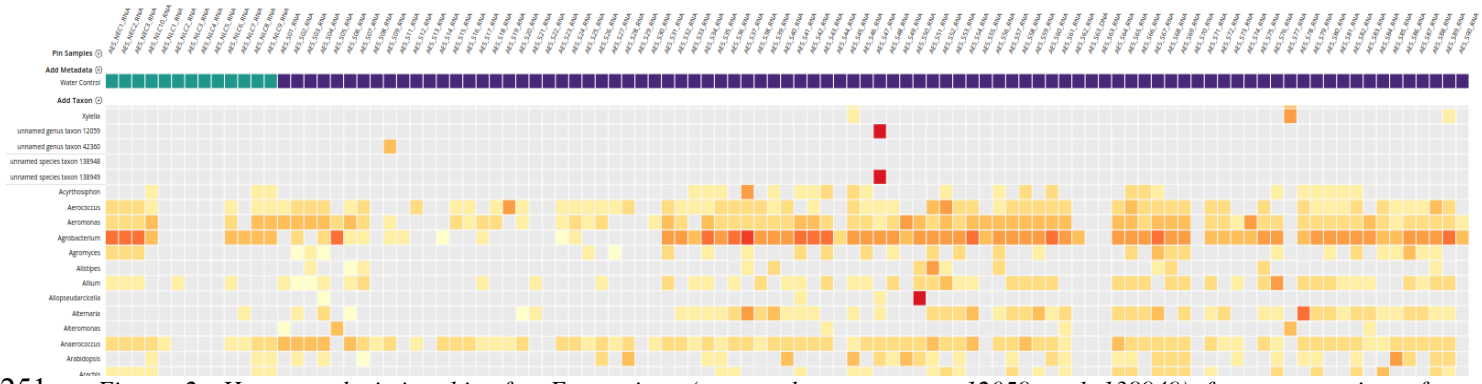

Figure 2: Heatmap depicting hits for Enterovirus (unnamed genus taxon 12059 and 138949) from sequencing of AES_S47_RNA. The names of the samples are on the top of the heat map. The samples marked by green are water controls during extraction (NEC) and library preparation (NLC). The heatmap was generated using the threshold of NT rPM (nucleotide reads per million) >=10 and NT L (alignment length in basepairs: length of the aligned sequence)>=50

In figures 1 and 2, we can see top hits of organisms in the heat map that shows various organisms which are seen at similar levels in the water controls as well. Nevertheless, Pseudomonas genus is seen

in all of the samples including few negative controls. There was similar trend, in both sets, with other organism such as Sphingomonas, Acinetobacter, Escherichia and others.

Interestingly, only AES_S47_RNA showed a hit to Enterovirus B. This hit was particular to sample 47 and not seen in any negative controls. The metrics such as rPM of 359,409.1 (provides information of the abundance of a specific microbe within the sample), NT L (depicts the length of aligned sequence in base pair), Z score of 99 (shows the significance of any hit compared to the background), coverage visualization (assess breadth and depths of reads) and id of 85.8% signify that the organism hit is highly similar to the reference organism.[30] The figure below shows the abundance of Enterovirus B in Sample 47 (NT rPM >=10 and NT L >=50). The coverage breadth of this hit was 98.7% with depth of 700.4x as seen in Figure 3.

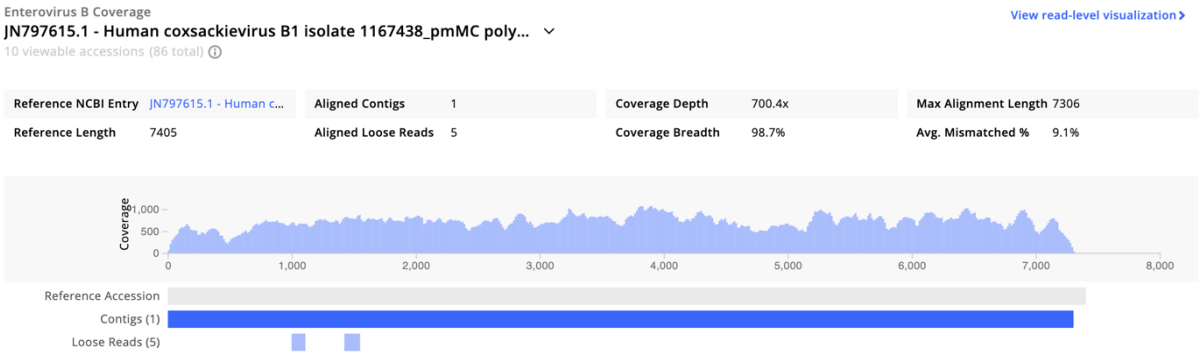

Figure 3: Coverage visualisation of Enterovirus in AES_S47_RNA from CZID, depicting the coverage metrics of the contigs generated for the particular hit along with coverage depth and width. The hit was visualised with the threshold of NT rPM >=10 and NT L >=50.

mNGS of DNA Libraries

In mNGS of DNA libraries, hits were observed for Human alphaherpesvirus 2 [AES_S28_DNA] from the first set. The same sample showed hit for Human alphaherpesvirus 1, but in a very low abundance. Additionally, background contaminations (laboratory and hospital) were seen in the water controls in this DNA sequencing result as well. Similar to RNA Libraries, most of the samples showed hits for Sphingomonas spp., Pseudomonas spp, or Acinetobacter spp. Nevertheless, the following figure depicts the result of the hit where there were 2,598.6 rPM for Human alphaherpesvirus 2.

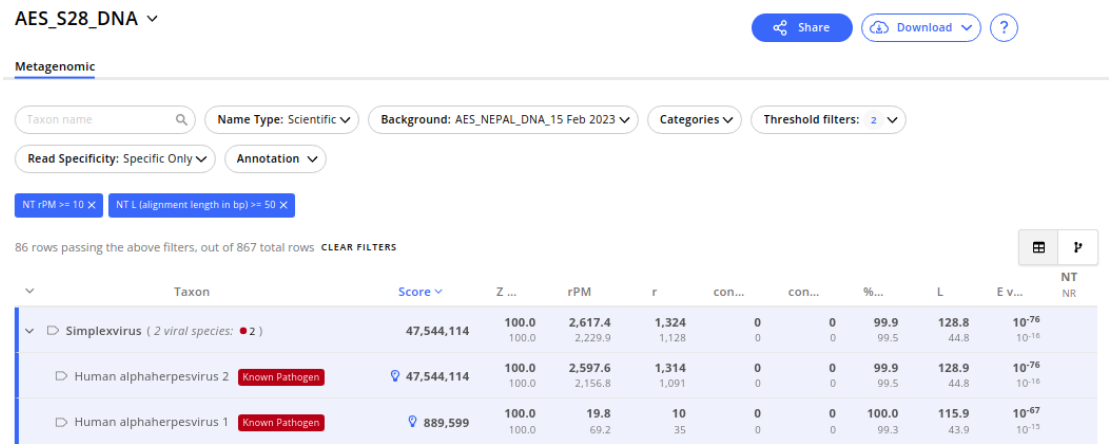

Figure 4: Result from CZID depicting the details of top hits in AES_S28_DNA along with various metrics related to the hit. The hits were visualised with the threshold of NT rPM >=10 and NT L >=50.

However, due to lower coverage, contig visualization was not available for this hit.

PCR Confirmation

Confirmation of Human alphaherpesvirus 2

Out of the two primer sets used, the established primers fared better providing Ct value of 23.11 for Human alphaherpesvirus 2.

Confirmation of Enterovirus B

After completion of snPCR for Enterovirus, the band was seen between 700-800bp after first amplification and between 300-400bp after final amplification. This confirmed the presence of Enterovirus as per the Enterovirus Surveillance Guidelines.[29]

DISCUSSION

Demography of Acute Encephalitis Syndrome

Most of the subjects suffering from acute encephalitis syndrome (AES) were young male population of median age 20 years. This gender distribution was concurrent to previous studies done, in Nepal, on epidemiology of AES.[31,32] It has been observed that AES affects individuals from both gender and all ages, however, most of the studies have been done in younger population, as they pose high risk due to lack of developed antibodies.[33,34,35,36] Another study done in Nepal also observed the young median age (19 years) for AES, while others observed older population.[31,32,37,38]

Metagenomic Next Generation Sequencing

In this study, out of the 90 samples tested, most (n=88) of them could not be specified as specific hits. This was due to high level of background contaminants resulting in low confidence in calling organism

315 hits within the experimental samples. Nevertheless, two samples showed confirmed hits for Enterovirus
316 B and Human alphaherpesvirus 2, respectively. The absence of causative agent in remaining samples
317 indicate that either the samples did not have intact nucleic to start with or were degraded.[16,39] Extended
318 storage in uncontrolled conditions could also be a likely contributing factor for the degradation.
319 As per the result of mNGS, the high Z score (99) for Enterovirus B shows that hit for the organism is
320 present significantly in our sample, when compared to the background. The average length of
321 alignment (as shown by L metrics) is long (L=7258.7), which confirms for a good local alignment to
322 reference.[40] The id% is also higher (85.8%) meaning that the organism is highly similar to the reference
323 organism in the database. Additionally, when the genome coverage is seen in detail, we can see that our
324 sequenced genome depicts good coverage breadth and depth (depth of 700x and breadth of 98.7%),
325 which is the range and uniformity of sequencing coverage for the particular hit.[39] The presence of
326 ENVB was also confirmed through snPCR followed by visualization of product size specific for all
327 enteroviruses.[29]
328
329 The hit for alphaherpesvirus 2 was considered significant because it was not present in the control
330 samples at the thresholds used to analyse the sample (high Z score of 100%, L value of 128.9, id% of
331 99.9%) considered reliable.[24,27,41] The low contig value, for this hit, could be because of the organism
332 being present at such a low abundance that the sequencer did not sequence enough reads to generate a
333 contig. The contig value is dependent upon the total number of reads and the size of organism's
334 genome.[42] Additionally, the decreased sensitivity of mNGS due to low abundance of pathogen has been
335 studied for CSF.[43] Several methods have been reported that can be used to increase the abundance of
336 pathogen sequences or remove the unwanted host sequences.[44,45] Nevertheless, as this genus is
337 associated with encephalitis, the sample was taken further for analysis.[46,47] During confirmation, the
338 lower Ct value of 23.11 indicates presence of alphaherpesvirus 2, a known causative agent, in the
339 sample.
340
341 **Enterovirus B and Human Alphaherpesvirus 2**
342 Enterovirus B is a known causative agent of encephalitis.[16,48,49,50] Enteroviruses are named by their
343 transmission-route through the intestine.[51] Studies have shown that enterovirus can cause various
344 diseases in the nervous system, including aseptic meningitis, acute paralysis, encephalitis, meningo-
345 encephalomyelitis among others, in children.[52,53,54] Interestingly, studies in India have linked
346 Enterovirus, among other pathogens, to AES, by various studies.[55,56,57] For instance, Enterovirus

347 outbreak was first reported from Uttar Pradesh, India in 2006 with seasonal outbreaks with high fatality
348 occurring for several years.[55,58,59] Southern Nepal borders with UP, India and due to open borders and
349 similar climate, it is no surprise that Enterovirus was found in AES infected CSF sample from Nepal.
350 Additionally, some studies in Nepal have reported Enterovirus as possible etiology of AES for
351 Nepal.[60,61]
352
353 Similarly, Human alphaherpesvirus 2 is known to cause encephalitis in neonates and
354 immunocompromised patients. Herpes simplex encephalitis (HSE) has significant morbidity and
355 mortality, even with early diagnosis and treatment.[62,63] HSV is found to be one of the predominant
356 causes of AES in the western world.[64,65,66] Among herpes simplex encephalitis, the vast majority of the
357 encephalitis is caused by HSV-1, with HSV-2 being the etiology in less than 10% of the cases.[63] Studies
358 in India and Nepal have reported the presence of HSV-2 as causative agent of encephalitis, with
359 varying range of incidence. [61,67,68,69,70, 71]
360
361 **Clinical Data and Process Control**
362 However, due to lack of proper clinical metadata, the presence of Enterovirus B and Human
363 alphaherpes 2 virus could not be clinically correlated. Clinical metadata such as onset of fever, date of
364 infection, fatality, WBC counts, adjoining infection, etc are vital to correspond with the presence of
365 infections.[16,72,73] Additionally, usual environmental contaminants such as Sphingomonas spp.,
366 Pseudomonas spp, or Acinetobacter spp were seen. For instance, Sphingomonas are widely distributed
367 in nature, having been isolated from many different land and water habitats, as well as from plant root
368 systems, clinical specimens, and other sources. This is essentially due to their ability to survive in low
369 concentrations of nutrients.[74,75] Background contaminations of laboratory and hospital origin were also
370 seen in the water controls. With appropriate use of background or negative controls, a background
371 model can be created and subsequently subtracted from the results.[16,24]
372
373 **Collection Procedures**
374 The lack of identification of causative agent in other 88 samples could be because the majority of
375 samples were degraded prior to extraction. The samples that were analysed were as old as 2016 and
376 2017, and were collected without stringent or consistent guidelines. They could have gone through
377 numerous freeze and thaw cycles. Moreover, the sample could have gone through degradation prior to
378 storage depending upon how they were transported from the site of collection. The causative agents

379 could also have left the cerebrospinal fluid prior to collection. Collection of samples in nucleic acid
380 protectant such as Zymo RNA/DNA Shield would have protected the nucleic acid from degradation
381 after sampling.[76,77]
382
383 We postulate that the results of this study should not be corroborated as limitations as the CSF samples
384 analysed were not collected specifically for mNGS. The lack of stringent collection procedures and
385 sample quality are likely limiting to the analysis, resulting in ambiguous interpretation of some
386 samples. Additionally, the sequencing was done in Illumina iSeq100 which has a maximum of
387 approximately 4 million reads per run and can only accommodate a certain number of organisms with
388 adequate coverage breadth and depth.[78]Additionally, host depletion and pathogen enrichment methods
389 can be applied for samples with low pathogen abundance.[44,45]
390
391 **CONCLUSION**
392 From this study, two documented, causative agents were revealed through metagenomic next
393 generation sequencing and subsequently confirmed by PCR. Insufficiency of clinical metadata, process
394 controls, and absence of standard operating procedure to collect in nucleic acid protectant incorporates
395 ambiguity when correlating identified pathogens to infections. Therefore, there is a dire need of
396 implementing stringent collection procedures for sample collection, including proper process controls.
397 Additionally, delicate samples such as CSF should be collected in a protectant and transported in a
398 controlled and sterile environment. Collection of clinical metadata such as WBC count, primary
399 diagnosis, discharge type and presence of other known organisms are vital for the analysis.
400 Identification and investigation of etiologies behind AES is essential for developing clinical
401 management algorithms, improving surveillance with region-specific treatment and prevention policy
402 as well as outbreak investigation. We do not expect the administration of mNGS as a regular diagnostic
403 tool but rather an investigational and exploration tool to identify causative etiologies and develop
404 molecular methods (such as qPCR) for diagnosis.
405
406 **Declaration of competing interest**
407 We declare that we have no potential conflicts of interest.
