Abstract

In a previous paper [1] a simplified SEIR model applied to COVID-19 cases detected in Italy, including the lockdown period, has shown a good fitting to the time evolution of the disease during the observed period.

In this paper that model is applied to the initial data available for Italy in order to forecast, in a qualitative way, the time evolution of the disease spreading. The values obtained are to be considered indicative.

The same model has been applied both to the data relating to Italy and to some italian regions (Lombardia, Piemonte, Lazio, Campania, Calabria, Sicilia, Sardegna), generally finding good qualitative results.

The only tuning parameter in the model is the 'incubation period' τ.

In this modelization the tuning parameter, together with the calculated growth rate κ of the exponential curve used to approximate the early stage data, are in strong relationship with the compartments' transfer rates.

The relationships between the parameters simplify modeling by allowing a rough (not supported by statistical considerations) forecast of the time evolution, starting from the first period of growth of the diffusion.

Revision # 1

- Errata corrige in the system differential equation 1: in the the derivative of S were reported a wrong additional term N. Now the equation 1 is correct.

1 Introduction

A simplified SEIR compartmental model seems to fit quite well the evolution of COVID-19 during the period of social isolation in Italy [1]. In this paper the model is used to forecast the diffusion behavior starting from the initial stage of infection growth.

The dataset is the same of the previous paper [1] and is available on the website [2] managed by italian government. The model used is a simplification of the Susceptible-Exposed-Infected-Recovered type (see [3], [5], [4]) and the simplification is based on the relationships between the model parameters and the growth rate of the exponential curve in the early stage of diffusion (see [1]). The dataset cover a period where after a initial growth of the COVID-19 diffusion a 'lockdown' period, characterized by strong social isolation rules, were imposed to act effectively against the rapid spread of the disease.

The lockdown period, simplifying, can also be thought of as a type of treatment for infective individuals. We can therefore imagine that infective individuals, detected daily, in general are managed ('treated') in such a way that they cannot infect other susceptible individuals. This 'treatment' includes both hospitalization and isolation. To avoid confusing the SEIR model with this simplification, in this context, we will call T (Treated) the compartment of infected people who are no longer able to transmit the pathogen.

The social isolation, also allows us to neglect any potential transfers between the various departments beyond the required path $S \to E \to I \to T$. The 'treated' compartment in this case can be seen as a sample of individuals in whom the disease has been widespread and the spread is characterized by the model coefficients. The significance of the sample is related to the number of detections of the disease, and their distribution, carried out in the population.

The model can be set up easily once initial the growth rate is calculated and a suitable value for the incubation period is defined. In this work the data used are normalized to 1000 individuals in order to generalize the results. The first part of data, in the growing period, are used to calculate κ, the remaining data are used for comparison with the model's forecasting.

2 Conclusions

A simplified compartmental model [1] can be used to easily predict a qualitative behavior of a disease diffusion starting from the early stage. It is obviously necessary that the number of detections of the disease and their distribution, carried out in the population, are statistically significant, in this case the simplified model can be used to roughly estimate the qualitative behavior of the spread.

The only tuning parameter in the simplified model is the 'incubation period' τ. In this modelization the tuning parameter, together with the calculated growth rate κ of the exponential curve used to approximate the early stage data, are in strong relationship with the compartments' transfer rates. The relationships between the parameters simplify modeling by allowing a rough (not supported by statistical considerations) forecast of the time evolution, starting from the first period of growth of the diffusion.

3 Model parameters and detection criteria

The key parameters needed to set up a simplified SEIT model are (see [1]):

- the incubation period τ;
- the rate k calculated in the first approximation of the initial exponential growth $y(t) = y_0 e^{kt}$.

It is important to note that the exponential growth k in this simplification appears as a dimensionless number. To avoid confusion we will use κ for the dimensionless parameter.

It is assumed that the number, the quality and the distribution of tests to detect the disease in the population are statistically significant; in this case, using the simplified SEIT model it is possible to easily characterize, in a qualitative way, the disease diffusion in the compartments S,E,I,T over time.

The system of differential equations for the simplified model $S \to E \to I \to T$ is:

$$\begin{cases} \dot{S} &= -\alpha_{SE}\dfrac{I}{N}S \\ \dot{E} &= \alpha_{SE}\dfrac{I}{N}S - \alpha_{EI}E \\ \dot{I} &= \alpha_{EI}E - \alpha_{IT}I \\ \dot{T} &= \alpha_{IT}I \end{cases} \tag{1}$$

where N is the total number of individuals : $N = S + E + I + T$ The temporal evolution follows a disruption of the equilibrium at $t = 0$:

$$\begin{bmatrix} S_0 \\ E_0 \\ I_0 \\ T_0 \end{bmatrix} = \begin{bmatrix} N-1 \\ 1 \\ 0 \\ 0 \end{bmatrix} \tag{2}$$

At $t = 0$ the number of individuals susceptible to the disease is $S_0 = N - 1$ and there is one individual exposed. In this work the data are normalized to 1000 individuals.

In this simplification it is assumed (see [1]) a relationship between κ and the transfer rates α_{xy} between the compartments x, y in the unique available path $S \to E \to I \to T$.

$$\begin{cases} \alpha_{EI} &= 1/\tau \\ \alpha_{SE} &= \alpha_{EI}/\kappa = 1/(\kappa\tau) \\ \alpha_{IT} &= \kappa\alpha_{EI} = \kappa/\tau \\ \alpha_{EI}^2 &= \alpha_{SE}\alpha_{IT} \\ \mathcal{R}_0 &= \alpha_{SE}/\alpha_{IT} = 1/\kappa^2 \end{cases} \tag{3}$$

where $\mathcal{R}_0$ is the basic reproduction number calculated as spectral radius of the next generation matrix (see [3], [4], [5]) in the simplified model (see [1]).

In order to estimate κ it is important to define a criteria to detect the initial growth in an effective way.

The criteria used in this context is that a new κ is calculated when the daily variation $\Delta\tilde{T}_t$ of the detected cases exceed the last maximum of daily variation.

$$\Delta\tilde{T}_t > max(\Delta\tilde{T}_j) \ ; \ j = 0...t \tag{4}$$

The new κ is calculated as:

$$\kappa_t = \frac{log(\tilde{T}_t/\tilde{T}_0)}{t} \tag{5}$$

where $\tilde{T}_0 = 229$ individuals 'treated' at $t = 0$ corresponding to 2020-02-24 (see table 2).

Table 1: *Records corresponding to the days when exceeding the last maximum daily variation value. The growth rate κ is calculated as per (5). The full dataset is in tab. 2*

For each record in tab 1, a κ (eq. 5) has been calculated and the corresponding value of the detected cases $\tilde{T}_t$ is used to synchronize the model. The model parameters are then easily found using eq. 3 with τ as tuning parameter. The model results and the available data are normalized to 1000 individuals.

After some trial, good τ values has been found within 4 and 6 days.

The next section 4 shows all results for $\tau = 5.2$ while in the subsection 4.1 some results for $\tau = 4$ and $\tau = 6$ are shown.

Table 3: *Parameters of the model referring to Italy. Each κ is calculated using the detection criteria and reported in tab. 1. The only tuning parameter is the incubation period τ that in this case is assumed to be 5.2 day. The basic reproduction number is calculated as spectral radius of the next generation matrix and in this simplified model (see [1] and eq. 3) is equal to: $\mathcal{R}_0 = \alpha_{SE}/\alpha_{IT} = 1/\kappa^2$*

The graphical results are shown in the following sections.

4 Graphic results for Italy

In all graphs the orange point represent the day where the daily differences exceeds the previous maximum daily difference. In that day an exponential parameter κ is calculated (see eq. 5).

The simplified SEIT model parameters have been found using the relations in (3) with the only tuning parameter τ corresponding to an 'average' incubation period. All data are normalized and refers to 1000 individuals. The detected data used to estimate the model are represented with a thick gray line ending with an orange point. The remaining data are represented with a thin grey line in order to be compared with the model forecasting (green line).

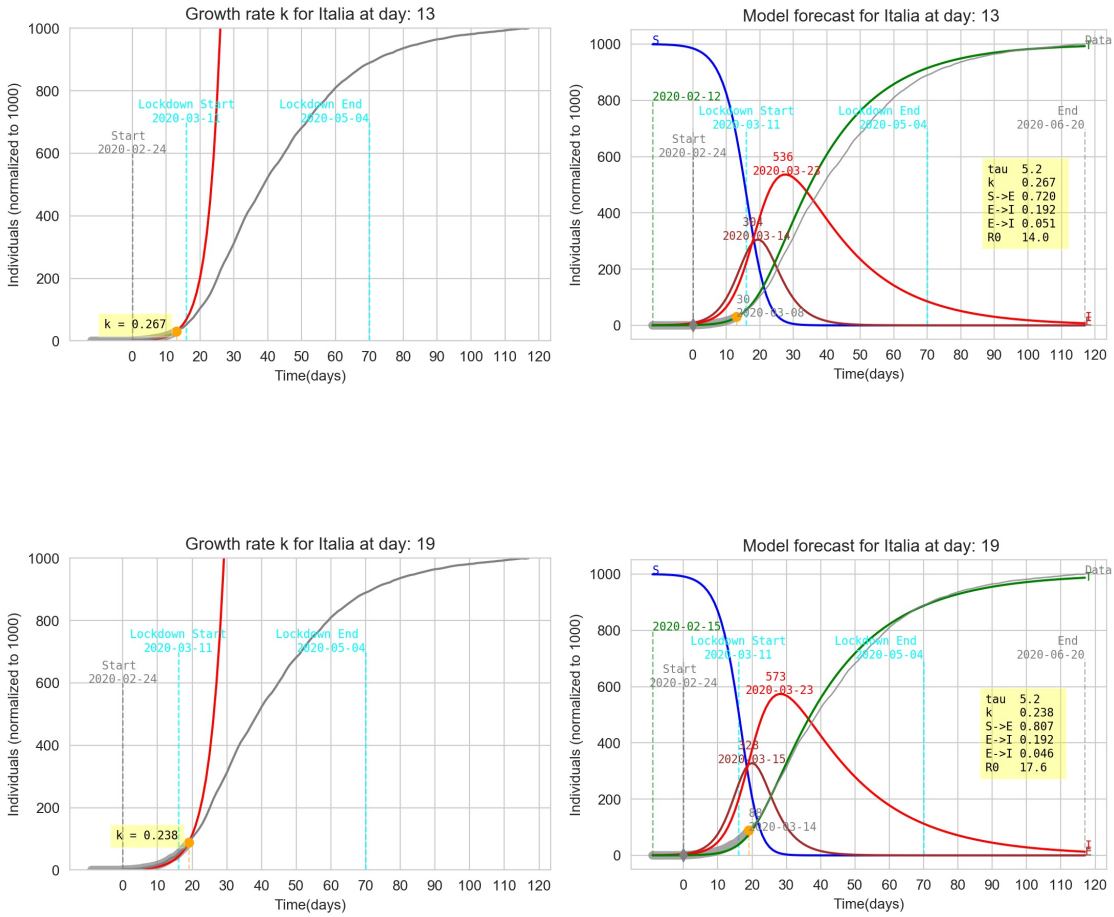
4.1 Sensibility to the tuning parameter

In order to have a qualitative feedback on the impact of the tuning parameter τ the graphs below represent the model for Italy with the detection κ calculated at $t = 13$ and $t = 19$ and three different τ between 4 to 6 days.



5 Graphic results for some italian regions

This section contains some results for several regions of Italy referred to two κ detected in the growth phase. The tuning parameter τ is different for each region and is in a range between 4 to 6.5 days.
