Abstract

Background. The nutritional status of communities susceptible to Buruli ulcer (BU, a skin NTD caused by infection with *Mycobacterium ulcerans*) remains almost completely obscure. We have assessed the diets of BU patients vs. controls from the same BU-endemic communities, and compared their circulating biomarkers of nutrients and inflammation.

Methods/Principal Findings. We investigated two cohorts of BU patients and controls. The first were administered food frequency and multi-pass 24-hour recall questionnaires to determine patterns of foods consumed, nutrient intake and nutrient adequacy. The second used archived serum samples collected as baseline to measure the circulating concentration of zinc, vitamin C, CRP, IL-1β, IFN-γ, TNF-α and IL-6. Stunted growth was more prevalent than expected (31%), while 18% of participants were underweight and most had inadequate intake of all micronutrients except for carbohydrate. BU patients had a lower intake of, selenium, vitamin B_{12} and zinc, and for selenium and vitamin B_{12} a higher proportion had dietary insufficiency (40% vs. 15% and 80% vs. 55%, respectively). In line with this, BU patients had significantly lower levels of zinc in their serum, and more had levels below the normal range (72% vs. 43%). Despite many participants having a good intake of vitamin C, serum levels were low, and lower amongst the BU patients. As expected, there was little evidence of systemic inflammation (CRP <0.6 mg/L). Elevated IL-6 levels were present in several participants suggesting that environmental enteric dysfunction may be prevalent in these communities, however this was similar in cases vs. controls.

Conclusions/Significance. Diet and nutritional status may be a contributing factor to BU pathogenesis. Protein and the micronutrients zinc, selenium, vitamin B_{12} and vitamin C may be of particular importance. Nutritional interventions may have potential for both prophylaxis and treatment of BU, which may be a cost-effective approach to achieving the NTD Roadmap goals.

Introduction

Buruli ulcer (BU) is a necrotizing skin disease caused by the non-tuberculous *Mycobacterium ulcerans* [1]. It is one of the neglected tropical diseases (NTDs) with skin manifestations [2], occurring as a painless nodule, plaque, oedema or ulcer [3]. A pathogen-derived exotoxin, mycolactone, is known to play a central role in disease pathogenesis [4, 5] due to its blockade the Sec61 translocon [6] underpinning its cytotoxic and immunosuppressive activities [7] as well as its induction of vascular dysfunction [8]. Hence, patients with BU do not have a systemic inflammatory response and generally present without fever or malaise even when ulceration is extensive [9, 10]. However, it is known that the immune system does control susceptibility to BU, with evidence from patients and animal models showing that macrophage function can influence infection outcomes [11-13].

Globally, BU is the third most prevalent mycobacterial disease and is commonly found in tropical or semitropical climates and most frequently in West Africa and Australia [1, 10, 14]. In Africa, the disease is widespread in poor rural communities with most cases found in children below 15 years. Even in high-resource settings, delays in treatment can result in permanent skin deformation or lifelong disabilities. Early case detection is currently the most effective approach for harm-minimisation as no vaccine exists.

To seek novel and cost-effective prevention approaches, and knowing that nutritional inadequacy is a risk factor for other mycobacterial infections (for example tuberculosis [15, 16] and leprosy [17, 18]) because it compromises immunity [19, 20], we postulated that this may also be the case for BU. However, there is a paucity of data for both BU patients and marginalised rural subsistence communities in West African countries. We, therefore, aimed to fill this knowledge gap by investigating the potential role of nutrition in the pathogenesis of BU.

Methods

Ethics

This study received favourable ethical opinion from the School of Medical Sciences Committee on Human Research, Publication and Ethics of KNUST (CHRPE/AP/18, CHRPE/AP/310/21) and the Faculty of Health and Medical Sciences Ethics Committee of the University of Surrey (UEC 2017 98 FHMS). All study participants gave informed consent.

Study area

BU patients were recruited from Agogo Presbyterian Hospital, Dunkwa Government Hospital, and Tepa Government Hospital in Ghana, which are located in areas of known BU endemicity. The archived serum samples were from previously published cohorts [21, 22].

Study design, population, and sampling

BU patients <5 years old, pregnant and lactating mothers were excluded from the study. Demographic and clinical data of cases was collected on a standardised skin NTDs [23] or BU01 form [21, 22]. The type and category of the lesion were assigned based on the WHO case definition [24]. Ulcerated lesions were dressed by nurses according to the WHO-recommended wound management protocol [24]. BU case confirmation was by a validated combined 16S rRNA reverse transcriptase/IS2404 qPCR assay [22] or IS2404 qPCR [21, 22].

Controls were recruited from the same study sites to ensure an unbiased reflection of the socioeconomic status, and food availability of the study population. Controls were age-sex-matched (as closely as possible) and residing in the same community of a recruited BU patient but from a different household.

Anthropometry

Anthropometric measures were obtained from as many participants as possible. Stratification of BMI was as advised by the WHO [25] including BMI-for-age estimation for participants 5-19 years [26, 27]. Anthropometry data had not been collected for the controls in Cohort 2. The height-for-age z-score (HAZ) was used to determine the stunting status of young people using AnthroPlus (WHO; Version 1.0.4.0) [27, 28].

Dietary assessment (Cohort 1)

A Ghana-specific food frequency questionnaire (FFQ) made up of 105 foods (**S1 Table**) was used to assess the frequency with which food items were consumed over the previous month at the time of recruitment (daily, weekly, monthly, and rarely/never) [29, 30]. These foods were divided into 25 food groups, using an approach adapted from a previous study of Ghanaian diets [31].

A Ghana-specific multi-pass 24-hour dietary recall questionnaire was also administered to obtain information on foods consumed for two week-days and one weekend day [32]. Household measures and food models were used to aid easy quantification of foods consumed, which were then converted into grams using a standardized unit of measure provided on a nutrient analysis template for each participant, which also estimated the nutritional content of these foods [33, 34]. Each participant's nutrient intake was compared to the relevant cut-off for their age (and gender if relevant), using information from the estimated average requirement (EAR) of FAO/WHO [35] or the RDA [36] if no EAR was available. The dietary diversity score (DDS) was also generated from the 24-hour recall data. This had 15 food groups (**S2 Table**) adapted from FAO guidelines for measuring household and individual dietary diversity [37], but with different numbers of food groups.

128 We assessed potential socioeconomic factors influencing the diets of participants
129 using a questionnaire to obtain data on the gender, household income, education level and
130 occupation of study participants. The household income was estimated based on the
131 reported household monthly income per individual. Some of the participants depended on
132 foodstuffs from their farms or livestock rearing. Those participants made an estimate on the
133 current cost of the foods consumed from their farms or livestock to help ensure accurate
134 determination of the monthly household income. Parents were allowed to make the
135 estimation of household income for their children.

136 The highest educational status of the participants was categorized into elementary
137 (none, primary or junior-high), secondary (senior-high and post-secondary) and higher
138 (tertiary education only) [38]. The occupation was grouped into formal or informal. Formal
139 included professionals, managers, clerical support staff, higher grade routine non-manual
140 employees service and sales-related occupations while informal consisted of craft and
141 related trades workers, elementary occupations (work that requires unskilled and semi-
142 skilled labour) and farmers[38].

143

144 **Quantification of nutritional and inflammatory biomarkers (Cohort 2)**

145 Vitamin C, zinc, and inflammatory markers were assessed in archived serum samples had
146 been stored at stable -80°C for up to 8 years. Vitamin C and CRP were assessed by
147 competitive and sandwich ELISA, respectively (MBS2700398, MBS8807458 MyBioSource,
148 San Diego, USA). Zinc quantification used a colorimetric assay (MBS841453 MyBioSource).

149 A bespoke Cytometric Bead Array (CBA) LEGENDplex™ (Biolegend, USA) was used
150 for the simultaneous detection of four cytokines [IL-1β (B326518), IL-6 (B326531), IFN-γ
151 (B326521) and TNF-α (B326522)] in 92 serum samples according to the manufacturer's
152 instructions.

Vitamin C and zinc concentrations were compared to normal ranges that have been determined in and for European populations [39-42]. We have no reason to believe that the nutritional requirements for Africans would vary widely from these values.

Statistical analysis

Data were analysed using GraphPad Prism version 9.4.1 (GraphPad Software Inc., USA). All continuous variables were tested for normal distribution. Non-Gaussian data compared medians between two groups using a one- or two-tailed Mann-Whitney-U test. Multiple comparisons used the Kruskal-Wallis test together with the Dunn`s post-hoc correction. Multiple t-tests were used to compare nutrient intake between patients and controls, as many nutrients correlated with each other (determined in Pearson correlation matrix). To compare the frequency of categorical variables we used Fisher's exact test or Chi-squared where there were more than two variables.

166 **Results**

167 **Characteristics of the study populations**

168 We recruited 40 confirmed BU cases and 40 controls in Cohort 1, and identified archived
169 samples from 80 confirmed BU cases and 80 controls in Cohort 2 (**Table 1**). The median age
170 of the cohorts was 19.5 (IQR 11-34) and 14.5 (IQR 10-27) years, respectively (range 5-63
171 years). In both cohorts the majority of cases presented with ulcers, and lesions were
172 predominately of Category I or II (80% and 73% respectively). Notably the rate of category III
173 lesions was higher in the most recently recruited patients (Cohort 1), probably due to the
174 disruption in case detection due to the COVID-19 pandemic. In line with the age profile of
175 Cohort 1, the approximately half had (or were having) primary school education, and the
176 socioeconomic profile was similar between cases and controls (**S3 Table**).

Table 1. Characteristics of study participants. Counts of demographic, clinical, and socioeconomic characteristics of study participants. [a]; Two-tailed Mann-Whitney tests, [b]; Fisher's exact test, [c]; χ^2 test (p-value < 0.05 was considered statistically significant), [d]; Anthropometric data was available for 69 BU patients and no controls in Cohort 2, [e]; Weight categorisation used BMI-for-age for study participants aged 5-19 [31], and BMI for adults, [f]; stunting according to WHO AnthroPlus. Abbreviation: SD; Standard Deviation, IQR; Interquartile range, N/A: not available.

While the majority of the participants had normal weight categorisation, 18.1% were underweight including 22.5% and 19% of BU cases and 12.5% of controls. In Cohort 1 the difference in proportion of underweight participants was not statistically significant (**Table 1**). Among the 86 young participants for whom we had anthropometry data, 27 (31.4%) had stunted growth (**Table 1**). The relatively low numbers in the subgroups make it hard to compare BU cases and control, but in Cohort 2, 3 out of 46 BU cases (7%) were categorised as being severely stunted.

Frequency of food consumption

The FFQ gave qualitative insights into the frequency with which Cohort 1 study participants ate foods within a range of different food groups (**S1 Fig**). Overall, this analysis shows that the participants in this study ate a fairly typical rural Ghanaian diet consisting of carbohydrate-rich foods. For example, whole grain cereals, refined cereals, fermented maize products, rice and pasta, roots/tubers/plantain were eaten frequently by more than half the participants (**S1A-E Fig**). This was alongside protein sources (predominantly chicken, fish and legumes **S1F, M&L Fig**), fruit (**S1J Fig**) and vegetables (**S1G-I Fig**). Some participants also partook in “Western” processed foods and drinks such as sodas and sweets/cakes (**S1O&Q Fig**), although more than three-quarters of the participants reported they never ate potatoes or processed meat (**S1R&Q Fig**). However, since the FFQ did not include a measure of quantity, it was hard to know how fully this meets the dietary requirements of the participants.

Nutrient intake and dietary diversity

A multi-pass 24-hour recall questionnaire was used to determine the overall energy and dietary macro and micro-nutrient intake of Cohort 1 study participants. This showed that, on average, the proportion of macronutrients making up the daily intake was close to expected

211 norms (**S4 Table**). In line with the FFQ, carbohydrate was the predominant nutrient in the
212 meals of both BU cases and controls (64% of daily energy intake), which is at the higher end
213 of expected norms (45-65%). On the other hand, protein made up the smallest portion of
214 energy intake (9.6%), at the lower end of the normal requirement of 10-35%.

215 While nutrient distribution was relatively normal, the energy intake (1629±638 Kcal,
216 **Table 2**) for the vast majority of the participants was inadequate, with only 15% meeting this
217 requirement (**Table 3**). For macronutrients, while almost all Cohort 1 participants had
218 adequate dietary carbohydrate, only 49% of the study population had inadequate intake of
219 protein (**Table 3**). There were no differences in total daily macronutrient intake between BU
220 cases and controls (**Table 2**)

221

Nutrients	All N=80 *Mean± SD*	BU Cases N=40 *Mean± SD*	Controls N=40 *Mean± SD*	P-value

	Inadequate	63 (79%)	30 (75%)	33 (83%)	
Zinc (mg)	Adequate	26 (32%)	12 (30%)	14 (35%)	0.812
	Inadequate	54 (68%)	28 (70%)	26 (65%)	

Table 3. Percentage adequacy of nutrient intake in Cohort 1 participants. Nutritional adequacy was determined using the Estimated Average Requirement (EAR) for all nutrients except for energy, fibre and vitamin K that do not have an EAR, and here Recommended Dietary Allowance (RDA) was used instead. Both vary depending on age, gender, height, pregnancy, and lactation (although pregnant and lactating mothers were excluded from the study). [a] two-sided Fisher's exact test. P-value <0.05 are indicated in bold text.

In terms of the micronutrient intake of Cohort 1, while the majority of the cohort had adequate intakes of dietary iron, selenium, and vitamin C (74%, 72%, and 82%, respectively, **Table 3**), >60% had inadequate intakes of dietary vitamin A (60%), vitamin B_{12} (68%), vitamin E (86%), vitamin K (79%), and zinc (68%). For most micronutrients, there was no statistically significant difference in nutritional adequacy between BU cases and controls. However, a higher proportion of BU patients were below the EAR for dietary selenium and vitamin B_{12} compared with the controls (**Table 3**). Moreover, when comparing the mean intake of micronutrients calculated from the 24-hour recall interviews, selenium, vitamin B_{12}, and zinc were significantly lower in BU cases than controls (**Table 2**), and vitamin C was different with a P-value of 0.084.

There were no statistical differences in intake amongst those with different categories of BU lesion (**S2 Fig**), sex (**S5 Table**, except for folate in controls; p=0.018), or household income (**S6 Table**), although in some cases, this may have been driven by the power of our study.

A diverse diet is strongly associated with diet quality; therefore, we generated a dietary diversity score (DDS) for the participants. This showed the diversity of the foods consumed among 15 food groups over a period of 3 days. Overall, the DDS of this cohort were within acceptable ranges for both groups, with only 6 BU cases and 4 controls consuming foods from less than 5 of these food groups in this time period (**Fig 1**). However, the DSS for BU cases was significantly lower than in the controls (6.2 vs. 7.2, p = 0.0320).

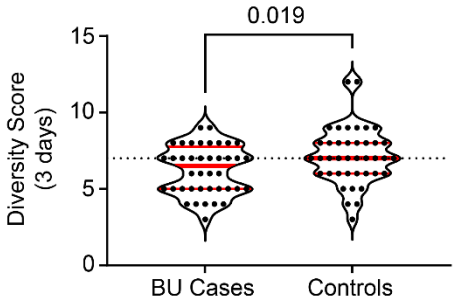

Fig 1. Comparison of dietary diversity between BU cases and controls. The dietary diversity score (DDS) was generated from 24-hour recall data obtained from all 80 Cohort 1 participants (40 BU cases, 40 controls), which assessed whether each participant ate any food from a particular group, out of 15, over the three days of the multi-pass (2 weekdays and one weekend day). The food groups for the were cereals, roots & tubers, green leafy vegetables, other vegetables, fruits, meat, fish & seafood, eggs, pulses & nuts, milk & milk products, oils & fats, sugar, condiments, drinks & beverages, and 'other'. Dietary diversity between BU cases and controls was compared using a two-tailed Mann-Whitney test. A p-value ≤ 0.05 was considered statistically significant.

Nutritional biomarkers

Based on these dietary data, we used archived serum samples to carry out a proof of principle that these dietary differences would translate to changes in serum concentrations, and selected zinc and vitamin C for analysis. The serum concentration of zinc and vitamin C was significantly lower in BU cases compared to controls (**Fig 2A**). Notably many BU patients and controls had levels below the expected normal ranges in serum, and this was significantly more frequent amongst BU patients than controls (P< 0.001, **Table 4**).

Severity of BU disease can be determined both by the different clinical presentations, and by the lesion category which is based on the longest diameter of the lesion (**Fig 2B&C**). There were no differences in the serum concentration of zinc or vitamin C between BU cases with less severe disease as defined by WHO category I, II or III lesion (**Fig 2B**), although a trend for lower vitamin C with increasing seriousness may have been limited by the few cases of Category III lesions in this cohort (n=6; 8%). However, BU patients with plaque forms had significantly lower levels of vitamin C compared to those who presented with nodules (**Fig 2C**), which are normally the first sign of infection.

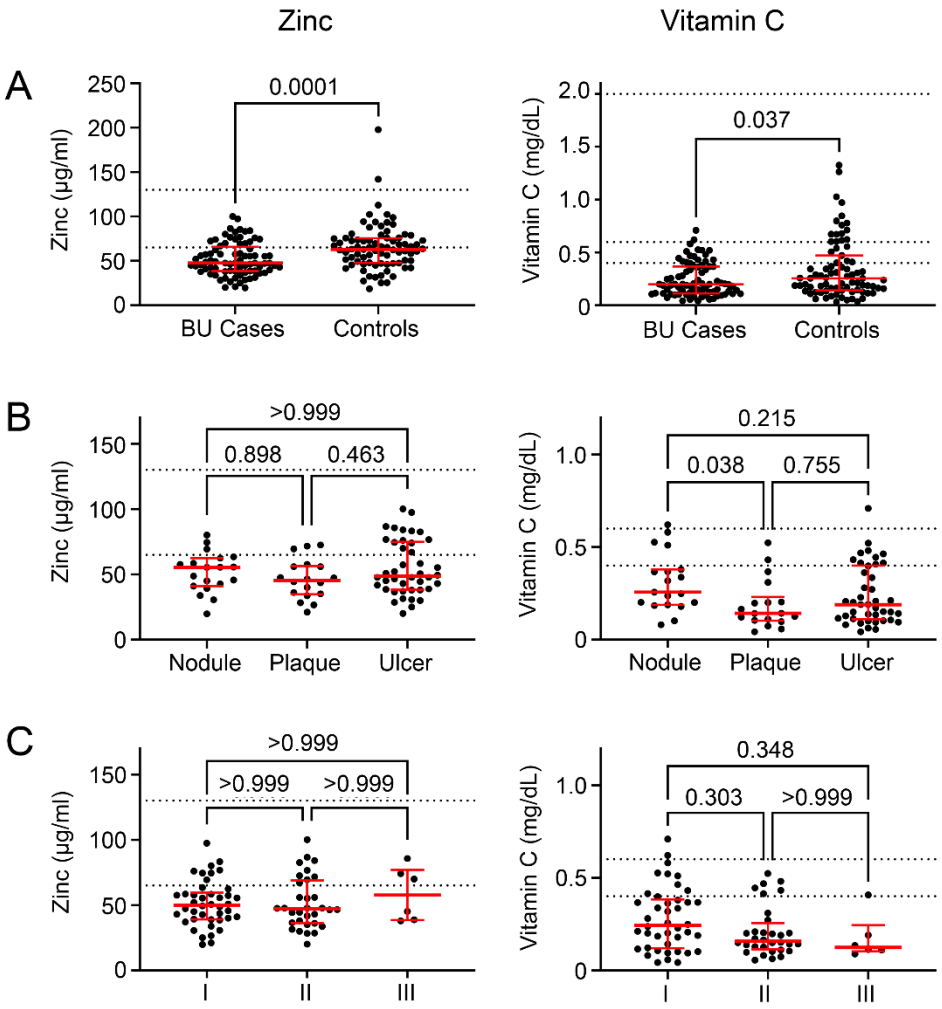

Fig 2. BU patients have significantly lower zinc and vitamin C serum levels than controls. The serum concentrations of zinc and vitamin C were assessed in BU cases and controls from Cohort 2 (40 BU cases, 40 controls). Individual data representing the average of duplicate assays is displayed along with the median and interquartile range. The expected normal ranges for each analyte are indicated with the dotted line (zinc 65-130µg/dL; vitamin C 0.4/0.6-2 mg/dL). P-values are displayed, with $P < 0.05$ considered significant. **A.** Data were compared using a one-tailed Mann-Whitney test. **B&C.** Subgroup analysis for BU cases with different clinical forms of the disease (N = 19, 18, and 42 for nodule, plaque and ulcer respectively, **B**) and different WHO lesion categories at presentation (N = 42, 32, and 6 for category I, category II, and category III lesions respectively, **C**). Data were compared between groups using the Kruskal-Wallis test and Dunn post-hoc test for non-parametric data.

289

Markers	Description	Threshold	All, N (%)	BU Cases, N (%) N=80	Controls, N (%) N=80	P-value[a]
Zinc	Normal	>60 µg/dL	68 (42%)	22 (28%)	46 (57%)	0.0002
	Reduced	≤60 µg/dL	92 (58%)	58 (72%)	34 (43%)	
Vitamin C	Normal	>0.6 mg/dL	19 (12%)	2 (3%)	17 (21%)	0.0003
	Reduced	≤0.6 mg/dL	141 (88%)	78 (97%)	63 (79%)	
	Normal	>0.4 mg/dL	72 (45%)	16 (20%)	56 (70%)	<0.0001
	Reduced	≤0.4 mg/dL	88 (55%)	64 (80%)	24 (30%)	

290 **Table 4. Serum zinc and vitamin C below the normal range are more common in BU**
291 **patients than controls in Cohort 2.** [a] Fisher's exact test with $P < 0.05$ considered
292 statistically significant.

293

294

295 **Inflammatory biomarkers**

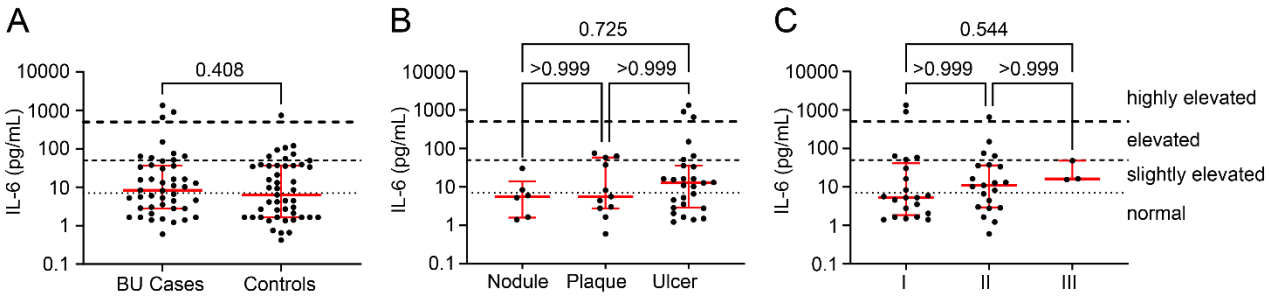
296 The serum levels of CRP, IL-1β, IFN-γ, TNF-α and IL-6 were also assessed in a subset of
297 Cohort 2. However, with the exception of IL-6, many samples had circulating levels below
298 the detection limit of the assays. Therefore, we took an approach that assigned each
299 participant within a threshold (**Table 5**). No participants had levels of CRP that indicated the
300 presence of even "high-normal" [43] levels of CRP. For IL-1β, we chose a cut-off of 57pg/ml,
301 and only 7-13% of Cohort 2, respectively, were above this level, (**Table 5**). For TNF-α and
302 IFN-γ we choose two cut-offs, with 2-5% having levels above the higher cut-off. There was
303 no statistically significant difference between BU cases and controls for these parameters.

304 For IL-6, such cut-offs are less well-defined than for CRP, but better defined than for
305 other cytokines, including by systematic review that showed the range of IL-6 measured in
306 cohorts of healthy patients was from 0-43.5pg/ml [44], although other reports from the global
307 North report at the lower end of this (2-3pg/mL [43, 45, 46]). Hence, for our analysis, we
308 decided to stratify our data based on whether they were normal (<7pg/ml), slightly (7-
309 50pg/ml), moderately (50-500pg/ml) or highly (>500pg/ml) elevated (**Table 5**). The proportion

310 of BU cases and controls in these different criteria were not statistically different, and neither
311 was there a difference in serum IL-6 levels (**Fig 3A**). There was no significant increase in IL-
312 6 levels within the presentation of BU (**Fig 3B**), nor the category of lesion (**Fig 3C**). However,
313 like vitamin C, this may be due to the small number of category III lesions.

314 However, this analysis showed that more than half of both groups had evidence of
315 elevated IL-6 compared to literature reports in European populations (**Table 5**). In order to
316 understand if these elevated levels of IL-6 might explain the reduced zinc or vitamin C with
317 IL-6, these were correlated (**S2 Fig**). No significant associations were identified for BU
318 patients (**S2A Fig**) or controls (**S2B Fig**).

319



320 **Fig 3. IL-6 levels are not significantly different between BU patients vs controls,**
321 **between BU lesion forms or lesion category.** Serum IL-6 was quantified in 45 BU patients
322 and 47 controls and presented on a $\log_{10}$ scale. **A.** Data for patients and controls were
323 compared using a two-tailed Mann-Whitney test. **B.** Levels were compared between BU
324 patients with different clinical presentations of the disease (Nodules, N=6; Plaques; N=11
325 and Ulcer; N=27), using the Kruskal-Wallis test with Dunn's correction for multiple
326 comparisons. **C.** Levels were compared between BU patients with different WHO lesion
327 category at presentation (Category I; N=21, Category II; N=21 and Category III; N=3), using
328 the Kruskal-Wallis test with Dunn's correction for multiple comparisons. GraphPad Prism
329 version 9.4.1 (GraphPad Software Inc., USA) was used for all analyses. P values are
330 displayed, with $P < 0.05$ considered significant.

333 **Table 5. Comparable serum concentration of inflammation markers in patients and**
334 **controls in Cohort 2.** Inflammation markers serum level concentration of study participants
335 grouped according to thresholds that indicate the degree to which the marker was elevated.
336 Numbers in each category were compared using contingency tables, using Fisher's exact or
337 chi-square tests with $P < 0.05$ considered statistically significant. [a] Includes 67 patients and
338 72 controls whose CRP levels were lower than the detection limit of the assay. [b] Includes 32
339 patients and 36 controls whose IL-1β levels were lower than the detection limit of the assay. [c]
340 Includes 28 patients and 30 controls whose TNFα levels were lower than the detection limit of
341 the assay. [d] Includes 18 patients and 24 controls whose IFNγ levels were lower than the
342 detection limit of the assay. [e] Participants in slightly elevated and elevated categories had to
343 be combined for this analysis. [f] Elevated and highly elevated categories had to be combined
344 for this analysis.

345

346

347

348 **Discussion**

349 The intimate links between diet, the immune system, and infectious disease have been
350 known for some time [47]. Indeed, malnutrition has been shown to be a predominant
351 underlying cause of death from a range of infectious diseases [48, 49]. Inadequate dietary
352 intake results in decreased immune function which leads to increased incidence of

353 infection/disease and consequently increased severity and duration of disease as the
354 systemic and local responses to infection are impaired. In addition, many infectious diseases
355 lead to decreased intake or malabsorption of, or increased requirements for, proteins (amino
356 acids), specific fatty acids, vitamins and trace elements. The increased metabolic demand
357 for specific nutrients can also lead to their deficiency leading to a vicious cycle of the
358 emergence of new infections or resurgence of old infectious diseases.

359 Perhaps because of the perceived dominant effect of the cytotoxin mycolactone in
360 disease progression, the role of diet in BU has received little attention to date. In the current
361 work, we show that many of those living in BU endemic regions of Ghana have diets
362 inadequate in all macronutrients except carbohydrates, as well as vitamins A, B_{12}, E and K,
363 and zinc. Moreover, BU patients' diets were worse than their control counterparts who had
364 similar age and socioeconomic backgrounds and who were also from the same villages as
365 the BU patients (and therefore had access to similar foods). Our approach to nutritional
366 intake used two independent tools, both of which have been used previously in rural and
367 urban Ghanaian settings [32, 50]. These were appropriate for low-literacy populations which
368 was the case here, and for those who reside in rural and at times remote communities.

369

370 **Insights into the diet of BU endemic areas**

371 The WHO defines malnutrition as the deficiency or excess of nutrient intake, an imbalance of
372 nutrients or impaired nutrient utilisation in children and adults. Undernutrition can manifest in
373 different ways including wasting, stunting, underweight and micronutrient deficiencies. On
374 the other hand, excessive nutrients can cause overweight or obesity. Women, infants,
375 children, and adolescents are at particular risk of malnutrition, and poverty exacerbates the
376 risk of malnutrition [51].

377 This study showed that those living in BU endemic regions in the Ashanti region of
378 Ghana had a typical rural West African diet [31, 52], which is mainly carbohydrate-based.

379 The diets of Ghanaians have been undergoing an evolution over recent years, particularly in
380 urban areas [53], where diets are shifting towards a 'Western-like' pattern [52, 54]. However,
381 the present study confirms that in rural areas, the dietary pattern has remained
382 predominantly carbohydrate-based. Apart from socio-cultural beliefs [54], the accessibility
383 and relatively cheap cost of starchy staples at the study sites may be the reason. Cereal-
384 based meals like akple, kenkey, and rice and root tubers like yam, cassava, and cocoyam
385 (used in preparation of staples like fufu and ampesi), were the most consumed by the study
386 participants. Fufu is a well-known staple food in Ghana and is eaten by most ethnic groups
387 and is prepared by pounding cassava and plantain or yam/cocoyam, and is consumed with
388 soup. Additionally, phytate content of plant-based diets will reduce absorption of
389 micronutrients including zinc and iron.

390 Despite the high proportion of calories from carbohydrate, the estimated requirement
391 was not met by most of the Cohort 1 participants. Other studies have also reported
392 nutritional inadequacies in rural (but not urban) Ghana [31, 50, 55]. Moreover, the energy
393 intake was lower than reported for people in Eastern and Southern Africa, which were 2245
394 and 2618 Kcal/capita/day, respectively [56]. This suggests that diets in BU endemic areas
395 are poorer than African averages, highlighting the need for further research to understand
396 nutrition in such marginalised communities. Indeed, this is the first study to report in the diets
397 of people in these areas of Ghana.

398 Protein in the diets of the study participants was inadequate in about 50% of the
399 participants. This was in line with a cross-sectional study that found low protein consumption
400 more often in rural Ghana compared to people residing in urban areas and migrants in
401 Europe [31]. Moreover, in a wildlife-depleted farm-forest landscape in South-Western Ghana,
402 between 14% and 60% of households ate less than the recommended daily allowance of
403 protein [57]. Although livestock rearing is common in the study sites, Cohort 1 participants
404 frequently ate fish and poultry, and rarely ate red or processed meat. The cost of meat could

405 be a factor affecting the low protein intake, with the majority of the protein coming from
406 starchy staples, which may then reduce the intake of some essential amino acids.

407 In terms of micronutrients, Cohort 1 also had a high prevalence of dietary inadequacy
408 of vitamins A, B_{12}, E, K and zinc. In line with this, overall micronutrient intake has been
409 shown to be inadequate in other studies of diet in West Africa and Ghana. This is thought to
410 be because they are mostly found in the vegetables, fruits, and nuts that are found in the
411 soups, stews, and sauces that accompany the main starchy component of a meal [58-61].
412 While, some micronutrients can be found in carbohydrate-rich foods, including roots and
413 tubers that were frequently consumed by Cohort 1 participants, their low DDS could be the
414 source of this inadequacy. This is because it suggests that many of them ate from a
415 relatively small palette of foods on a regular basis.

416 In the context of a population at risk of BU, the widespread inadequacy of
417 micronutrient intake is interesting because they are essential for immune function [20] and
418 are also seen in patients with chronic wounds. For example, inadequacies of serum vitamins
419 A, E, zinc, and carotenes have been reported in patients with chronic leg ulcers [62]. During
420 the inflammatory stage of wound healing, vitamin E helps reduce free radical damage
421 caused by neutrophils [63]. On the other hand, vitamin K is necessary for the functionally
422 essential post-translational modification of proteins involved in blood coagulation, which is
423 known to be linked to the histopathology of the disease [8, 64, 65]. Inadequacy in vitamin K
424 is known to cause haemorrhage and purpura in newborns and has recently been shown to
425 affect bone and vascular health [66]. Zinc status has previously been reported to be low in
426 Ghana [67] (prevalence of zinc deficiency ~22% in 2005 [68, 69]), and the prevalence of
427 zinc deficiency in Sub-Saharan Africa varies between 15-50%. The current work found
428 higher prevalence of zinc deficiency at 58%, further emphasising the poor quality of BU
429 endemic diets compared to the country at large.

430

431 **Potential role for environmental enteric dysfunction (EED) in malnutrition in BU**
432 **endemic areas**

433 Despite finding no overt systemic inflammation in BU cases, we did find evidence for
434 circulating cytokines above normal levels (low pg/ml concentrations) in a proportion
435 (approximately 10-50%) of both cases and controls of Cohort 2. Indeed, this is in line with
436 studies of healthy controls in other low- and middle-income countries (LMICs), including
437 Ghana [70-72]. Of particular note, elevated IL-6 levels were measured in more than half the
438 participants. This likely reflects participants who were currently or recently co-infected with
439 other pathogens. For instance, malaria infection can modulate circulating cytokines [73].
440 However, it could also reflect a prevalence of environmental enteric dysfunction (EED), a
441 syndrome linked to areas of poor sanitation and hygiene that is characterised by weight loss,
442 and histopathological evidence of chronic infection without a clearly diagnosed infection
443 being present [74]. Notably it can cause stunting in children and here approximately one
444 third of the young participants had stunted growth, adding further weight to this hypothesis.
445 This is higher than national and regional prevalence, which in 2022 was reported to be 17%
446 (20% in rural areas) and 17% in the Ashanti region in under 5 year olds, respectively [75].
447 One of the consequences of EED is malabsorption of nutrients (with the best evidence for
448 zinc) [76], which could potentially affect the interpretation of our findings. On the other hand,
449 IL-6 levels did not correlate inversely with those of zinc, suggesting that the degree of
450 systemic inflammation in patients was not sufficient to cause the physiological and molecular
451 changes that resulted in hypozincaemia [77]. Moreover, they were observed in the absence
452 of a high level of CRP, which would be an indication of systemic inflammation [78]. Additional
453 specific studies aimed at identifying EED, co-infections and systemic inflammation would be
454 required to find out if this is a general feature of the population and whether this influences
455 BU susceptibility and/or pathogenesis.

456 One interesting and unexpected finding was that, despite vitamin C having similar
457 prevalence of dietary sufficiency (82%) and generally a good intake in their diets, many

458 participants had serum vitamin C levels below the assumed normal range (55-88%
459 depending on the cut-off used). This could potentially be attributed to these measurements
460 being taken from two independent cohorts. However, both cohorts came from the same
461 distribution of BU-endemic communities surrounding Agogo, Tepa and Dunkwa, ruling out
462 local availability of food. Moreover, since BU disease has become less common, both
463 cohorts were recruited over a long period (Cohort 1; July 2018 to Mary 2022, Cohort 2;
464 October 2008 to June 2016), and therefore experienced similar seasonal variation in food
465 availability. Therefore, it seems that even in the setting of adequate vitamin C intake, this did
466 not translate to normal circulating vitamin C. This could be due to several factors, including
467 that the main source of vitamin C is likely to be stews that may have been boiled for
468 extensive periods, meaning that the intake was an over-estimate as the nutrient was
469 destroyed [79]. It is also possible that participants over-estimated their intake during the 24-
470 hour recall for psychological reasons or that EED could contribute since intestinal
471 inflammation may be a confounding factor in vitamin C status [67, 74] as it is absorbed in the
472 jejunum and ileum.

473

474 **Insights into the role of diet in the pathogenesis of BU**

475 While we could see no difference in the patterns of foods consumed between the BU cases
476 and controls in the FFQ, the 24-hour recall showed that the cases consumed diets with a
477 significantly lower DDS than the controls. This is in line with our findings that macronutrient
478 intake (predominately carbohydrate) was similar between BU cases and controls, but the
479 intake of micronutrients was different. In other words, it suggests that the lower dietary
480 diversity of the BU patients could be one cause of the lower micronutrient intake due to the
481 narrower range of foods eaten. In the context of a predominantly carbohydrate diet, a recent
482 mouse study is of interest when considering underlying risk factors for BU in this population.
483 Here, a ketogenic diet was modelled using b-hydroxybutyrate (the main ketone body
484 produced in such diets), and this suppressed skin ulceration by stopping *M. ulcerans* growth

485 and mycolactone synthesis with contrasting results observed in mice with a carbohydrate-
486 rich diet [69]. Therefore, the bacterium seems to require a diet rich in carbohydrates for
487 growth and mycolactone production, which is more than adequately provided by the diet of
488 the participants.

489 When considering micronutrient differences in detail, cases' diets contained
490 significantly less selenium and vitamin B_{12} and they were more likely to have dietary
491 insufficiencies of these micronutrients. Vitamin B_{12} deficiency is prevalent in regions with a
492 high burden of NTDs including helminth infection, Chagas disease and leprosy [80].
493 However, vitamin B_{12} was recently shown to be an important host-requirement for Mtb
494 infection, as it has lost the biosynthetic machinery for this vitamin [81]. In contrast, selenium,
495 a trace element, is required to clear mycobacteria [15]. In *M. tuberculosis* infection, selenium
496 was shown to have a restricting function against MTB by regulating autophagy in
497 macrophages contributing to low levels in patients compared to controls [82].

498

499 *Zinc*

500 Another of the largest differences in micronutrient intake between BU cases and controls
501 was in zinc, which was 20% lower in cases. Here we were able to confirm, in an independent
502 cohort, that serum levels were similarly 25% lower in cases than control. Moreover, BU
503 patients were much more likely to have serum zinc levels below that of the assumed normal
504 range than control counterparts. We are confident this represents a genuine micronutrient
505 deficiency, since CRP levels were extremely low in both groups (below 0.05 mg/dL) so we
506 did not need to correct this [83]. Moreover, our IL-6 data supports that both cases and
507 controls had equal exposure to other infections and/or EED, and hence BU is associated
508 with an additional reduction in zinc. Our findings relating to circulating cytokines are in line
509 with previous reports of BU, which were found to be either unchanged or reduced compared
510 to control groups [70, 84]. This is thought to be due to the anti-inflammatory activity of

511 mycolactone, which blocks the Sec61 translocon, causing a sharp reduction in the
512 production of proinflammatory cytokines that are reliant on Sec61 for secretion [6].
513 Therefore, while it is difficult to separate cause vs. effect for micronutrient measurement, our
514 finding that BU patients' nutritional intake of zinc was lower than controls supports a
515 nutritional component to the susceptibility to disease.

516 For BU patients, inadequate zinc may be implicated in disease susceptibility and
517 progress due to the role that this mineral plays particularly in the immune response. Indeed,
518 zinc supplementation has been reported to be an effective solution for immune recovery and
519 wound healing [85]. Zinc deficiency has been shown to decrease the production of TNF-α,
520 IFN-γ and IL-2 by peripheral blood mononuclear cells [86]. Zinc deficiency is reported to
521 increase susceptibility to leishmaniasis and TB [87], and in TB and leprosy hypozincaemia
522 has been observed at the time of diagnosis [17]. In leprosy, there is a gradual reduction in
523 serum zinc concentration as severity moves from Tuberculoid Leprosy to Lepromatous
524 Leprosy, affecting Th1/ Th2 cytokine responses [88]. Furthermore, in humans, low serum
525 zinc concentrations in cases with cutaneous leishmaniasis increase during antimonial
526 therapy. This may be due to pre-existing zinc deficiencies or related to redistribution
527 associated with the APR of visceral leishmaniasis [87, 89].

528

529 *Vitamin C*

530 The findings for vitamin C are more difficult to interpret. When comparing BU cases with
531 controls, intake of vitamin C was >30% higher in BU cases of Cohort 1 although this did not
532 reach statistical significance. On the other hand, serum levels were 20% lower in Cohort 2,
533 and a higher proportion of BU cases had abnormal serum levels that was highly significant.
534 Furthermore, within the BU cases, there was also an association between BU lesion
535 category and serum levels of vitamin C (in Cohort 2). Indeed, those with the more serious
536 plaque form of the disease had significantly lower vitamin C serum levels than those with its

537 earliest presentation, the nodule. Since all nodules are Category I lesions, it is notable that
538 the few Category III lesions in Cohort 2 were all associated with vitamin C levels below the
539 lower limit of the normal range. While these were approximately half those of the Category I
540 group, this difference did not reach statistical significance, perhaps due to the low numbers
541 in this sub-group.

542 Therefore, while acknowledging that dietary and biomarker data were collected in
543 different cohorts, our data suggests that the presence of *M. ulcerans* infection itself can
544 affect vitamin C status. Notably, others have found this to be the case in patients with sepsis
545 [90] and a cross-sectional analysis of the NHANES database found a negative correlation
546 between inflammatory markers and vitamin C [39] possibly due to increased demands from
547 the inflammatory response. Although vitamin C levels did not correlate with IL-6 in the
548 current work, it may be that the presence of chronic, localised inflammation in BU patients is
549 influencing the vitamin C levels in these patients.

550 Vitamin C is well-known to have important functions in skin health [91] as it is
551 required for the production and stability of collagen [91, 92]. Furthermore, a deficiency in
552 vitamin C dysregulates both phagocytosis and the respiratory burst [93]. The stimulation of
553 proinflammatory and Th1 cytokines is lower during vitamin C deficiency as it alters redox
554 signalling, essential during differentiation of Th cells [94]. We speculate that mycolactone's
555 known effect on extracellular collagen [8, 95] could synergise with these lower vitamin C
556 levels to have serious consequences for skin integrity.

557

558 **Limitations and conclusion**

559 There are some limitations that should be noted in this study. Here, dietary patterns and
560 dietary intake of the study group were assessed using methodological tools that rely on the
561 memory of the subjects, which can be biased. It is known that participants tend to
562 underestimate or overestimate dietary recalls, especially in food frequency questionnaires,

563 even though efforts were made to reduce possible biases to the minimum. The study also
564 includes two independent cohorts of BU patients and controls that were matched as closely
565 as possible. In Cohort 2, anthropometry data was not collected when these were recruited,
566 and so could not be reported It was not possible to determine the inflammation markers in all
567 patients, and our attempt to measure vitamin B_{12} in this same cohort was subject to assay
568 failure.

569 Despite these limitations, these findings align with two recent independent reports of
570 BU patients in Côte d'Ivoire [96, 97]. While there was no information on controls, in one
571 study, 51 BU patients also ate predominantly starchy foods and minimal proteins; indeed,
572 dairy products, fruits, vegetables, and vegetable oils were consumed by only 8% of the
573 cases [97]. Their food choices were found to be influenced by societal norms where food
574 types were prohibited in their communities, including certain animal and plant proteins,
575 vegetables, and fruits. Being underweight tended to be higher in Côte d'Ivoire vs Ghanaian
576 BU cases (33-53% vs 19-23%), and acute malnutrition was also reported [97]. Interestingly,
577 CRP levels >20 mg/L were reported in 7-20% of the cases, suggesting that EED may be
578 more prevalent in Côte d'Ivoire. However, in a subset of these patients and similar to here,
579 zinc was found to be below normal levels in all BU patients [96]. Importantly, nutritional
580 assistance provided at one health centre significantly improved wound healing alongside
581 marked improvement in anthropometrics and anaemia compared to another where no
582 nutritional support was included in BU patients' management package [97]. Taken together,
583 the findings strongly support large scale randomised control studies for nutritional
584 intervention in at-risk communities for BU and nutritional support for all BU patients,
585 alongside a detailed assessment of the prevalence of EED and how this may influence
586 susceptibility to BU and other NTDs.

Acknowledgement

The authors would like to thank all study participants and community leaders. We would like to express our utmost gratitude to all nurses, diseases control officers, and physiotherapists from Agogo Presbyterian Hospital, Tepa Government Hospital and Dunkwa Government Hospital for their support in patient management. We are grateful to the District Directors and the National Buruli ulcer Control programme. We thank Dr Peter Williams of University of Surrey, FHMS for statistical advice. This work was funded by a Wellcome Trust Investigator Award to Prof Rachel Simmonds (WT202843_Z_16),the Nestle Foundation (Lausanne, Switzerland) and the University of Surrey.

Supporting information Captions

Figure S1. The most and least frequently consumed food groups by the study participants. A food frequency questionnaire was put to all 80 Cohort 1 participants (40 BU cases, 40 controls), covering a total of 105 foods from 25 food groups. There are 4 possible answers for frequency of consumption for each food, namely daily, weekly, monthly, and rarely/never. This figure visualises the distribution of the most frequent consumption of one or more foods in that food group in the past month amongst the participants. The red line represents the frequency of consumption, and its length is proportional to the number of participants with that maximal frequency. Data from the food groups showed that at least 60% of the participants ate foods from these food groups at least weekly, where similar numbers consumed foods monthly, rarely or never vs. weekly or daily (N-Q), and those where at least 60% of the participants ate them monthly, rarely or never (R-Y).

Figure S2. No correlation between nutrition and inflammation markers in BU cases and controls. Serum concentrations of vitamin C, zinc and IL-6 were analysed using Spearman's correlation, and are presented as a heatmap. Spearman's correlation coefficients are given along with P-value (in brackets).
