**Abstract (150/150)**

We investigated whether differences in gut microbiome development could underlie differential susceptibility to gut colonization with extended-spectrum β-lactamase-producing Enterobacterales (ESBL-E) over time among children in peri-urban Lima. Weekly stool and daily surveys were collected from 345 children <3 years old during a 2016-19 study of enteric infections. A subset of children (n=12) were rarely gut-colonized with ESBL-E from 1-16 months of age. We performed short-read metagenomic sequencing of stool collected at 3, 6, 7, 9, 12, and 16 months from these children and a random subset of 42 frequently colonized children, and characterized differences in antibiotic use, sociodemographic characteristics, and the gut microbiome over time. No gut microbiome differences were identified, but rarely colonized children were more likely to live in households of lower socioeconomic status and consumed fewer antibiotics. Differences in exposures, rather than gut microbiome development, might underlie patterns of ESBL-E gut colonization among children in peri-urban Lima.

## Introduction (3497/3500 words)

Antimicrobial-resistant (AMR) pathogens are a public health threat, particularly in low- and middle-income (LMIC) countries like Peru where the infectious disease burden remains high. Gut colonization with extended-spectrum β-lactamase-producing Enterobacterales (ESBL-E), which are resistant to 3rd generation cephalosporins, is common among children living in shantytowns of LMIC cities and is a risk factor for infections, particularly in healthcare settings.(1–5)

Previous studies in low-resource settings have sought to identify risk factors for children's ESBL-E acquisition.(6–8) However, it remains unknown why some children are rarely or never colonized with ESBL-E, while others raised in the same settings are persistently gut-colonized. Intestinal "colonization resistance" refers to the ability of gut microbiota to inhibit colonization and overgrowth of exogenous bacteria.(9) Identifying microbial taxa that inhibit children's gut colonization with ESBL-E over time, as well as early-life exposures that support the assembly and maintenance of these protective taxa, could be helpful in designing future interventions to protect children's health.

Our team recently led a prospective birth cohort study of enteric infections among 345 children living in a shantytown of peri-urban Lima. We previously used culture-based methods to characterize children's gut colonization with ESBL-producing *Escherichia coli* and ESBL-producing *Klebsiella* spp., *Enterobacter* spp., and *Citrobacter* spp. (KEC) at or near 1, 3, 4, 5, 6, 7, 9, 12, and 16 months of age for a subset of 112 children enrolled in the cohort study.(4) We noted that while most children were frequently gut-colonized with ESBL-E over time, a fraction (n=12) were rarely or never colonized. Here, we investigated whether differences in gut microbiome development could underlie differing patterns of susceptibility to ESBL-E gut-colonization among this population.

## Methods

medRxiv preprint doi: https://doi.org/10.1101/2024.11.06.24316595; this version posted November 8, 2024. Stool collection

Stool samples were collected during a prospective cohort study of childhood enteric infections in Villa El Salvador, Lima, Peru (NIH R01AI108695-01A1).(4) Pregnant women were identified through an initial population screening in the community and through community health centers. Full-term babies were enrolled approximately within one month after birth from February 2016-May 2017, and daily surveillance data were collected through at least two years of age. Starting at recruitment and weekly thereafter, caregivers also kept a freshly soiled diaper for field worker collection. Upon arrival at a local lab facility, stool was aliquoted and stored at -20°C for up to 48h, then transported to UPCH for long-term storage at -80°C.

Sample selection

As previously described,(4) Enterobacterales were cultured from weekly stool samples of all newborns enrolled after December 2016 (112/345). For each sample, Enterobacterales colonies were pooled then archived. Colonies collected at approximately 1, 3, 4, 5, 6, 7, 9, 12, and 16 months of age were later screened for ESBL production. We observed two distinct patterns: children who were never or rarely colonized with ESBL-E (n=12), hereafter "*rarely colonized*," and children who were often or always colonized (n=100), hereafter "*frequently colonized"* (**Figure S1**). Rarely colonized children first tested positive for ESBL-E at approximately 6 months or later, and were colonized at fewer than half of tested timepoints. Frequently colonized children were colonized at more than half of timepoints.

Exposure assessment

As previously described,(4,10) socioeconomic variables were collected at recruitment and then once yearly. Additionally, field staff visited infants every day except Sunday to collect survey data from the previous 24 hours. If field workers were unable to visit an infants' home (e.g., day

medRxiv preprint doi: https://doi.org/10.1101/2024.11.06.24316595; this version posted November 8, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. No reuse allowed without permission.

was Sunday), field workers collected survey data for the missing day at the next visit. At each daily visit, caretakers were asked about children's milk consumption, antibiotic use, and diarrhea in the past 24 hours. Caretakers were asked to provide medication packaging so trained field workers could confirm it was an antibiotic. Because survey data were collected daily, this packaging was typically available. A new antibiotic course began when caretakers reported antibiotic consumption following two days of no exposure; a course ended when the child did not consume antibiotics for two consecutive days. Children were considered to have had diarrhea if they experienced ≥ 3 liquid or semiliquid stools in the past 24 hours.

Metagenomic sequencing

We performed short-read metagenomic sequencing on available frozen stool specimens collected at approximately 3, 6, 7, 9, 12, and 16 months of age from all rarely colonized children (n=12 children, n=71 stool samples), and a randomly selected subset of 42 frequently colonized children (n=238 stool samples). Total DNA was extracted from approximately 0.25 g of frozen feces at UPCH using the QIAamp PowerFecal Pro DNA Kit (Qiagen) according to manufacturer's instructions and quantified using a Qubit 4 fluorometer (Invitrogen). Extraction blanks were included with each batch of extractions; DNA concentrations were below the Qubit level of detection (<0.1 ng/µL) for all. DNA extracts were sent to the Broad Institute for short-read, paired-end 150 bp sequencing on an Illumina Novaseq 6000 System using SP4 flow cells to achieve 6 Gb per sample.

Processing metagenomic data and profiling taxonomy

Fastq sequences were trimmed and filtered to remove sequencing adaptors and low quality reads using bbmap.(11) We tabulated the number of raw reads for each sample and excluded from further analysis any sample with more or less reads than two standard deviations from the mean (n=11). Human contaminant sequences were removed from each sample by discarding reads that mapped to a non-redundant version of the Genome Reference Consortium Human

medRxiv preprint doi: https://doi.org/10.1101/2024.11.06.24316595; this version posted November 8, 2024. Build 38 (GRCh38; www.ncbi.nlm.nih.gov) using Bowtie2 v2.5.1. Human sequence-filtered raw reads were deposited in the Sequence Read Archive (SRA; https://www.ncbi.nlm.nih.gov/sra) under the project number PRJNA1138246 (**Table S1**).

Taxonomic assignment of short reads was performed using MetaPhlAn3 (with db v31).(12) Alpha diversity metrics were derived from the MetaPhlAn3 relative abundance output using the vegan package in R [https://cran.r-project.org/web/packages/vegan/].

Data analysis

We examined differences in sociodemographic characteristics, diarrhea rates, and antibiotic use between rarely and frequently gut-colonized children using t-tests and chi square tests for all 112 children for whom we characterized ESBL-E gut colonization, and separately for the 54 children whose stool samples were sequenced.

For the subset of 54 children with fecal metagenomes, we examined whether any taxa were differentially abundant between rarely and frequently gut-colonized children across time using mixed effects linear regression models. An arcsine square root transformation was applied to relative abundance values. We also used mixed effects linear regression models to examine differences in log10 transformed species richness values and Shannon diversity over time between groups. Transformed relative abundance values and alpha diversity metrics were modeled as a function of subject (random effects term), colonization pattern, i.e., rarely versus frequently colonized (binary fixed effects term), child age (continuous fixed effects term), and hours before diaper retrieval (continuous fixed effects term). We also ran additionally parametrized models adjusted for factors known to affect the gut microbiome, including child's delivery mode (binary fixed effects term) and number of diarrhea episodes and antibiotic courses in the past 30 days (continuous fixed effects terms), as well as all socioeconomic characteristics that differed groups with $p<0.20$. We did not adjust for breastfeeding as there was minimal variation in this exposure over time (**Table S2**). All taxa with more than 10% non-

medRxiv preprint doi: https://doi.org/10.1101/2024.11.06.24316595; this version posted November 8, 2024. No reuse allowed without permission.

zero values were fitted using the nlme package in R. Significance of associations was determined using Wald's test, and p-values were adjusted for multiple hypothesis testing using the Benjamini-Hochberg correction at each taxonomic level.

For the subset of metagenomes for which we had matched ESBL-E gut colonization status, we examined whether any taxa were differentially abundant between timepoints where children were ESBL-E positive versus negative using mixed effects logistic regression models. For any given taxa detected in at least 10% of samples, we modeled ESBL-E positivity (yes/no) as a function of subject, child age, hours before diaper retrieval, number of recent diarrhea episodes and antibiotic courses, and the transformed relative abundance value of that taxa. We used the lme4 package in R and adjusted p-values using the Benjamini-Hochberg correction at each taxonomic level.

Finally, we used the StrainGE tool(13) to characterize *E. coli* strains in children's fecal metagenomes. A reference database was built using complete *E. coli* genomes from NCBI's RefSeq database (~3,100 genomes downloaded March 5, 2024), and each genome was assigned a Clermont phylotype using EzClermont v.0.70.(14)

## Results

### Children who were rarely gut-colonized with ESBL-E belonged to households of lower socioeconomic status

There were no significant differences in exposures that are well-known to impact the gut microbiome, including rates of vaginal birth, antibiotic consumption rates, children's age at time of first antibiotic consumption, or numbers of diarrhea episodes per child month between rarely versus frequently colonized children (**Table 1)**. Rarely colonized children did consume slightly fewer antibiotic courses overall (3.4 vs 4.5 courses/child-year, $p$=0.2), and fewer azithromycin courses in particular (0.1 vs 0.5 courses/child-year, $p$=0.14), but differences were not

medRxiv preprint doi: https://doi.org/10.1101/2024.11.06.24316595; this version posted November 8, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. No reuse allowed without permission.

statistically significant. Only 2/112 children did not consume any antibiotics, yet both were frequently colonized with ESBL-E.

Children who were rarely gut-colonized with ESBL-E did belong to households of lower socioeconomic status (SES). Specifically, they were somewhat more likely to live in households that relied on a public tap for drinking water ($p$=0.06) versus having an indoor connection, and more likely to rely on pit latrines versus indoor flush toilets ($p$=0.05). Most households that relied on water taps also used pit latrines, and vice versa. Rarely colonized children were also somewhat less likely to be born to a mother who had completed high school (p=0.11). Children's antibiotic use (total courses/child-year) was weakly correlated with household reliance on public water taps ($r_{pb}$=0.24, $p$<0.05 by point-biserial correlation) and use of a pit latrine ($r_{pb}$=0.25, $p$<0.05), but was not correlated with maternal education attainment ($r_{pb}$=0.04, $p$=0.67).

Breastfeeding was exceptionally common. On average, children received breastmilk nearly every day in the 30 days prior to a stool sample through 16 months of age (**Table S2**). Notably, nearly 1/3 children who were frequently colonized with ESBL-E regularly consumed formula early in life, compared to just 1 of 12 rarely colonized children (**Table 1**). However, this difference was not significant (p=0.29).

The distributions of these exposures were similar among the subset of 54/112 children whose fecal metagenomes were sequenced for this study (**Table S3**).

<u>Peruvian children's gut microbiomes are dominated by *Bifidobacterium* spp. regardless of ESBL-E colonization status</u>

Samples included in our final analysis included 66 fecal metagenomes from 12 rarely colonized children and 232 fecal metagenomes from 42 frequently colonized children (n=298 total, 4-6 samples per child).

medRxiv preprint doi: https://doi.org/10.1101/2024.11.06.24316595; this version posted November 8, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. As expected given the high proportion of breastfeeding in this setting, children's gut microbiomes were largely dominated by *Bifidobacterium* spp., comprising 58% of bacterial reads in average at 3 months, and 34% by 16 months (**Figure 1**). *B*. *longum* and *B. breve* predominated earlier in life, while *B. bifidium* consistently comprised between 10-15% of bacterial reads (**Figure 2**). The number of unique *Bifidobacterium* spp. in children's guts ranged from 0-9 (median=4) and increased as children aged (β=0.14, SE=0.019, *p*-value<0.0001). Pooling all timepoints together, there was no difference in the relative abundance of any *Bifidobacterium* spp. between children who were rarely versus frequently gut-colonized with ESBL-E. Likewise, the number of unique *Bifidobacterium* spp. did not differ between groups.

<u>No differences in diversity or relative abundance of gut bacteria between rarely and frequently colonized children</u>

Besides *Bifidobacterium*, other dominant bacterial genera included *Blautia* (average across all samples 3.1%), *Bacteroides* (2.1%), *Escherichia* (1.9%), *Lactobacillus* (1.1%), *Faecalibacterium* (0.9%), and *Klebsiella* (0.8%) (**Figure 1**). Potential enteropathogens like *Klebsiella pneumoniae* and *Enterococcus faecium* were detected among nearly all children (**Table S4**). After adjustment for multiple comparisons, no taxa were differentially abundant between children who were rarely versus frequently gut-colonized with ESBL-E over time in fully parameterized models (corrected p-values all > 0.89). Results were similar for simpler models that only adjusted for children's colonization pattern, child age, and hours before diaper retrieval (fdr-corrected p-values all >0.66).

Like others,(15) we found the number of unique bacterial species in children's fecal metagenomes increased as they aged, from 31 to 75, on average. The diversity of children's fecal metagenomes also increased (0.99 Shannon diversity index on average at 3 months, to 2.31 at 16 months) (**Figure S4**). Pooling all timepoints together, we observed no differences in diversity or richness between groups (p-values> 0.62). There were also no differences in

medRxiv preprint doi: https://doi.org/10.1101/2024.11.06.24316595; this version posted November 8, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. No reuse allowed without permission.

median richness or Shannon diversity at any specific sampling point (p>0.52 for all pairwise differences by Wilcoxon rank sum tests).

No differences in the number and diversity of *E. coli* strains between rarely vs frequently colonized children

Rarely colonized children appeared to harbor slightly fewer *E. coli* strains on average at each timepoint (**Figure 3A**), but these differences were not statistically significant (p>0.15 for all by Welch two-sample t-test). In general, children's stool samples were largely dominated by *E. coli* phylotypes A and B1 (**Figure 3B**). There was no significant difference in the proportion of strains belonging to any given *E. coli* phylotype between rarely and frequently colonized children at any time point (p>0.26 for all pairwise comparisons by Fisher test).

We also examined differences in *E. coli* strains between sampling points where children were gut-colonized with ESBL-E versus not (ESBL-E gut colonization status available for 263/298 fecal metagenomes). Overall, children harbored more unique *E. coli* strains at sampling points where they were gut-colonized with ESBL-E (mean=2.3 across all age groups) versus sampling points where they were not (mean=2.1, p=0.05 by Welch two-sample t-test), though there were no differences for specific sampling points (p>0.15 for all by Welch two-sample t-test). Overall, there was no difference in *E. coli* phylotype distribution at sampling points where children were gut-colonized with ESBL-E versus not (*p*=0.75 by Fisher test).

Some differences in relative abundance of specific taxa at ESBL-E positive versus negative timepoints

Regardless of whether children were rarely or frequently gut-colonized with ESBL-E over time, we did note that the relative abundances of the phyla *Actinobacteria* (average across all samples 45.9%; fdr-corrected p-value=0.20) and the genus *Slackia* (0.006%, fdr-corrected p-val=0.03) in children's stool were higher at timepoints where children were not gut-colonized

medRxiv preprint doi: https://doi.org/10.1101/2024.11.06.24316595; this version posted November 8, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. No reuse allowed without permission.

with ESBL-E by culture, when controlling for child age, hours before diaper retrieval, number of recent antibiotic courses and diarrhea episodes, and repeated measurements (**Figure S3**). Relative abundances of the phyla *Proteobacteria* (3.4%, fdr-corrected p-value=0.20), the phyla *Bacteroidetes* (2.9%, fdr-corrected p-value=0.20), and the class *Erysipelotrichia* (0.47%; fdr-corrected p-val=0.15) were higher at timepoints where children colonized with ESBL-E by culture.

## Discussion

This is the first longitudinal study of the gut microbiome among South American children. As previously reported, gut colonization with ESBL-E was prevalent among children in this peri-urban setting and steadily increased as children aged.(4) Similar to recent studies among healthy adults,(16–18) our findings suggest that differences in exposures, rather than differences in gut microbiome development, might underlie patterns of ESBL gut colonization over time among children in peri-urban Lima. To our knowledge, this is the first study to examine this research question among young children who are living in a low-resource setting and whose gut microbiomes are rapidly developing.

Three recent Western studies and two LMIC studies have investigated associations between gut microbial taxa and ESBL-E gut colonization at single time points.(16–20) Two case-control studies among Dutch(17) and French adults(18) found no differences in alpha diversity or taxa abundance between healthy adults who were gut-colonized with ESBL-E versus not, after controlling for age, sex, ethnicity, and recent travel. Another study among US travelers(16) found no difference in the pre-travel gut microbiomes of individuals who acquired ESBL-E while abroad versus those who did not, suggesting that differences in exposures while traveling, rather than inherent differences in intestinal colonization resistance, are more important determinants of ESBL-E acquisition. One study of healthy Thai adults(20) reported differences in gut taxa between ESBL-E carriers and non-carriers, but because potential

medRxiv preprint doi: https://doi.org/10.1101/2024.11.06.24316595; this version posted November 8, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. No reuse allowed without permission.

confounders were not controlled for, it is challenging to attribute differences to ESBL-E colonization status. A small study among indigenous persons in French Guyana identified some differences in gut microbial taxa between 8 cases and 24 controls, but whether these differences preceded or were a result of ESBL-E gut colonization could not be determined.(19) To our knowledge, no previous study has examined whether differences in the gut microbiome over time, rather than just at a single timepoint, may underlie ESBL-E gut colonization patterns. Our study adds to the existing literature by indicating that patterns of rare versus frequent ESBL-E gut colonization among children who are frequently exposed to enteropathogens and antibiotics may not primarily be a function of intestinal colonization resistance.

Taxa that previous studies have identified to be associated with ESBL carriage or non-carriage differed from what we observed. *Actinobacteria*, which typically dominate the guts of breastfeeding children,(21) were somewhat more abundant at ESBL-negative timepoints (fdr-corrected p-val=0.2), while *Proteobacteria*, *Bacteroidetes*, and *Erysipelotrichia*, all of which are commonly isolated in children's stool,(21) were somewhat more abundant at ESBL-positive timepoints (p-val between 0.15 and 0.2 for all). *Slackia*, which is not well-described among children but has previously been isolated from both gut and oral infections in adults,(22) was more abundant at ESBL-negative timepoints though overall abundance was low (0.006%). Differences between our study and previous work(19,20) could be a result of our focus on the pediatric microbiome, differences in our sequencing approach, differences in environmental exposures, or other factors. We note that whether these differentially abundant taxa preceded or followed ESBL-E gut colonization cannot be distinguished through our analytical approach.

Overall, the fact that we did not identify gut taxa that were differentially abundant between rarely and frequently colonized children could be because such differences do not exist; for example, perhaps the differential exposures we noted only affected the gut metabolome. There are other gut microbiome differences that we were unable to explore, *e.g.*, higher bacteriocin production among commensal strains harbored by rarely colonized children,

medRxiv preprint doi: https://doi.org/10.1101/2024.11.06.24316595; this version posted November 8, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. No reuse allowed without permission.

which could favor the exclusion of ESBL-E.(23) Or, we may have been underpowered to detect differences. Given the high and increasing rates of ESBL-E gut colonization in community settings in LMICs, we note that enrolling sufficient children to adequately investigate this research question may be challenging in future studies.

While we did not identify differentially abundant gut taxa or differences in *E. coli* strains between rarely and frequently colonized children, we surprisingly found that rarely colonized children were more likely to belong to households of lower SES. Although these differences were not statistically significant at the $p<0.05$ level, the households of rarely colonized children were somewhat more likely to lack access to indoor piped water and flush toilets, and their mothers were less likely to have completed high school. A previous study of drug-resistant urinary tract infections in women in Hyderabad, India, found that poorer women were most likely to have an ESBL-producing infection, despite consuming fewer antibiotics than wealthier women, suggesting environmental exposures unique to low SES populations might be underlying elevated risks of exposure to AMR bacteria in this setting.(24) We find the opposite trend here, with lower SES children having the lowest risk of being persistently colonized with ESBL-E early in life. The role of the environment as a source of exposure to ESBL-E likely differs among and perhaps within LMICs. We note that while multiple global analyses indicate that antimicrobial resistance is more common in LMICs compared to high-income settings,(25,26) many LMICs have high rates of income inequality and within-country heterogeneity in acquisition risks have rarely been examined.(27)

This study had strengths and limitations. Our study represents the first longitudinal analysis of the gut microbiome of South American children, whose fecal metagenomes are under-represented in global databases.(28) Because daily surveys were collected, we were able to control for time-varying exposures that are known to affect the gut microbiome, including antibiotic use and recent diarrhea, with a low risk of recall bias. However, our study was relatively small, and we may have been underpowered to detect differences in gut microbial

medRxiv preprint doi: https://doi.org/10.1101/2024.11.06.24316595; this version posted November 8, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in perpetuity. All rights reserved. No reuse allowed without permission.

taxa between groups. Further, as previously noted,(4) we used culture-based methods with a relatively high lower limit of detection (~2 log10 CFU/g wet feces) to identify ESBL-E gut colonization for this study. Rarely colonized children may have been gut-colonized with ESBL-E at timepoints where they tested negative, just at concentrations below the limit of detection. However, since higher concentrations of multidrug-resistant Enterobacterales in the gut are associated with elevated risks of infection,(29,30) identifying whether specific gut taxa may suppress the growth of ESBL-E remains a clinically relevant question.

## Conclusion

This study examined whether differences in Peruvian children's gut microbiome development could underpin differences in early-life susceptibility to ESBL-E gut colonization. We did not identify any significant differences in species richness, Shannon diversity, *E. coli* strain diversity, or the relative abundance of specific taxa between rarely versus frequently colonized children. Nevertheless, rarely colonized children who were somewhat more likely to live in households of lower SES. Regardless of gut colonization patterns over time, children harbored higher relative abundances of *Proteobacteria*, *Bacteroidetes,* and *Erysipelotrichia* at timepoints where they were ESBL-E positive and higher abundances of *Actinobacteria* and *Slackia* at timepoints where they were negative. Our findings are in line with recent studies among healthy adults(16–18) suggesting that differences in exposures, rather than differences in the gut microbiome, might underlie differing patterns of susceptibility to ESBL-E gut-colonization. Our findings suggest that preventing ESBL-E colonization among children in LMICs may require reducing their exposures to environmental reservoirs of ESBL-E.

## Data Availability

Children's fecal metagenomes are available in NCBI's Sequence Read Archive (https://www.ncbi.nlm.nih.gov/sra) under BioProject number PRJNA1138246.

## Ethics approval and consent to participate

The parent cohort study was approved by the Institutional Review Boards of Asociación Benefica PRISMA, Universidad Peruana Cayetano Heredia, and Johns Hopkins University. Written informed consent was obtained from caretakers of the infants for both study participation and the use of collected specimens for subsequent research. The analysis of stool specimens for this substudy was approved by the Institutional Review Boards of Asociación Benefica PRISMA and Universidad Peruana Cayetano Heredia (no. 201592). Metagenomic sequencing of stool specimens was determined to be exempt by the Tufts University Health Sciences IRB (STUDY00001328).

475 Tables

476 **Table 1**. Sociodemographic characteristics and early-life exposures among 112 Peruvian
477 children who were rarely or frequently colonized with ESBL-E during the first 16 months of life.

| | Frequently colonized (n=100) | Rarely colonized (n=12) | *p*-val |
|---|---|---|---|
| Male (n, %) | 48 (48.0) | 7 (58.3) | 0.711 |
| Birth mode (n, %) | | | 0.234 |
| Vaginal | 68 (68.0) | 10 (83.3) | |
| Cesarean section | 31 (31.0) | 1 (8.3) | |
| Missing | 1 (1.0) | 1 (8.3) | |
| Mother completed high school (n, %) | 69 (69.0) | 5 (41.7) | 0.117 |
| Water Source (n,%) | | | 0.063 |
| Other | 5 (5.0) | 0 (0.0) | |
| Public Tap | 15 (15.0) | 5 (41.7) | |
| Indoor water connection (24 hours) | 80 (80.0) | 7 (58.3) | |
| Toilet (n,%) | | | 0.051 |
| Other | 2 (2.0) | 0 (0.0) | |
| Pit latrine | 14 (14.0) | 5 (41.7) | |
| Indoor flush toilet | 84 (84.0) | 7 (58.3) | |
| Home has improved flooring[a] | 97 (97.0) | 11 (91.7) | 0.906 |
| Lives in household with more than six household members (n,%) | 40 (40.0) | 2 (16.7) | 0.207 |
| Received breastmilk 90% of days in first 3 months (n,%) | 63 (63.0) | 8 (66.7) | 1 |
| Received formula 50% of days in first 3 months (n,%) | 27 (27.0) | 1 (8.3) | 0.29 |
| Household owned chickens (n,%) | 17 (17.0) | 1 (8.3) | 0.721 |
| Total number of antibiotic courses per child-year (mean (SD)) | 4.45 (2.86) | 3.36 (2.29) | 0.207 |
| Number of azithromycin courses per child-year (mean (SD)) | 0.47 (0.95) | 0.06 (0.22) | 0.144 |
| Number of sulfa-trimethoprim courses per child-year (mean (SD)) | 1.03 (1.15) | 0.98 (1.09) | 0.888 |
| Number of amoxicillin courses per child-year (mean (SD)) | 1.59 (1.41) | 1.93 (2.36) | 0.471 |
| Number of cefalexin courses per child-year (mean (SD)) | 0.53 (0.90) | 0.32 (0.61) | 0.425 |
| Age in months at time of first antibiotic use (mean (SD)) | 5.67 (4.49) | 7.23 (3.75) | 0.251 |
| Number of diarrhea episodes/100-child-month (mean (SD)) | 6.88 (5.09) | 5.28 (2.59) | 0.288 |

478 [a]Improved flooring included cement, wood, tiles, and “falso piso.” Unimproved flooring included
479 dirt and sand.

Figures

**Figure 1**. Proportion of bacterial genera with at least 1% average relative abundance in stool samples collected from Peruvian children aged 3-16 months.

**Figure 2**. Relative abundance of dominant *Bifidobacterium spp.* in stool samples collected from Peruvian children aged 3-16 months.

*Note*: Fifteen *Bifidobacterium spp.* were detected among all children; species with at least 1% average relative abundance are depicted here.

**Figure 3**. Distribution of *E. coli* strains in stool samples from Peruvian children aged 3-16 months who were frequently vs rarely gut-colonized with ESBL-E, including A) mean number of unique *E. coli* strains, and B) Clermont phylotype.
