Abstract

Wastewater-based epidemiology (WBE) has been widely used to track viral pathogens like SARS-CoV-2 and polio, but its potential for monitoring common dental bacterial pathogens that infect the oral cavity has yet to be explored. *Streptococcus mutans* and *Porphyromonas gingivalis* are key oral bacterial pathogens that cause highly prevalent dental diseases worldwide, such as dental caries and gingivitis. Our main objective for this study was to investigate the presence and prevalence of these oral bacteria in wastewater to determine the feasibility of using WBE for oral pathogens. We measured *S. mutans* and *P. gingivalis* nucleic acids in weekly samples for 24 months at a local wastewater treatment plant. A total of 100 untreated wastewater samples were collected once a week between June 2023 and May 2025. Samples were concentrated, extracted for DNA, then tested for each bacterium. Our results showed that 89% and 58% were positive for *S. mutans* and *P. gingivalis*, respectively, which shows that wastewater surveillance is appropriate for oral bacteria. Average concentrations were 4.57 $\log_{10}$ genome copies/L and 3.03 $\log_{10}$ genome copies/L for *S. mutans* and *P. gingivalis*, respectively. Detections of oral bacteria were observed in the primary and final effluent but concentrations were significantly lower in the final effluent than untreated wastewater. The high levels of oral bacteria in wastewater indicated a potential transmission mechanism for these bacteria through water, specifically for *S. mutans*. Additionally, this study underscores the unique potential for WBE to be used in the surveillance of oral bacterial pathogens.

1.0 Introduction

Dental caries, or tooth decay, is one of the most prevalent chronic diseases worldwide, affecting nearly 2.3 billion people with permanent tooth decay and over 530 million children with primary tooth loss, according to the World Health Organization (Organization, 2017). *S. mutans* is a major culprit in dental caries, playing a significant role in plaque formation and acid production that demineralizes tooth enamel (Caufield, 2000; Forssten et al., 2010; Lemos et al., 2019). *P. gingivalis*, on the other hand, is a key pathogen in periodontal disease, a severe gum infection that can lead to tooth loss and systemic health complications which can include cardiovascular disease and diabetes (Marutescu et al., 2023; Rafiei et al., 2017). The high global burden of these oral health issues underscores the importance of developing innovative disease surveillance methods to understand the spread of these diseases.

Wastewater Based Epidemiology (WBE) has become increasingly popular in recent years as a tool to monitor the spread of endemic and emerging pathogens passively in a community. WBE has already been successfully employed to monitor various pathogens, such as SARS-CoV-2 and antimicrobial resistance genes, yet its application to oral bacteria remains largely unexplored (Greaves et al., 2020b; Rodriguez et al., 2024). Given the widespread presence of these oral bacteria in human populations, understanding their prevalence in wastewater can provide insights into community-level oral health trends and transmission dynamics. Traditional surveillance methods, such as clinical examinations and self-reported surveys, have limitations in reach, accuracy, and cost-effectiveness (Pitiphat et al., 2002; Sekundo et al., 2019). WBE, on the other hand,

67 allows for large-scale, community-wide monitoring without the need for individual
68 participation, offering a more comprehensive and real-time picture of oral health
69 burdens (Cohen et al., 2024; Daughton, 2020). If a strong correlation between
70 wastewater bacterial levels and oral disease prevalence is established, this approach
71 could serve as an early warning system for emerging trends in oral health conditions,
72 prompting timely public health interventions (Kasprzyk-Hordern et al., 2022; Mao et al.,
73 2020). However, there is no current public health surveillance system for the oral
74 diseases caused by these specific dominant pathogens at the national or local level.
75 Hence, our current understanding on the prevalence of these diseases within the past 5
76 years has been severely limited. Therefore, the use of WBE is especially timely in filling
77 the gaps in information about these oral pathogens.

78 Beyond monitoring, the detection of oral bacteria in wastewater raises concerns about
79 their environmental persistence and potential transmission pathways (Chopra et al.,
80 2020; Galarde-López et al., 2024). Although wastewater treatment processes are
81 designed to remove or reduce microbial contaminants, some pathogens can survive or
82 be reintroduced into the environment through treated effluent and biosolids by attaching
83 to particles (Chahal et al., 2016; Marutescu et al., 2023). If *S. mutans* and *P. gingivalis*
84 demonstrate resilience through treatment processes, there is a risk of environmental
85 exposure, which could have implications for public health (Huang et al., 2024; Li et al.,
86 2022; Rams et al., 2023; Sweeney et al., 2004; Teoh et al., 2018). Further studies are
87 needed to assess whether these bacteria can colonize environmental surfaces,
88 influence microbial ecosystems, or contribute to antimicrobial resistance.

In this study, we determined the concentration of *S. mutans* and *P. gingivalis* in wastewater samples over one year. We also determined the concentration of *S. mutans* and *P. gingivalis* in wastewater primary influent, primary effluent, and secondary effluent. Lastly, we observed the prevalence and persistence of *S. mutans* over time in influent wastewater by running a month-long decay experiment. By measuring the prevalence of *S. mutans* and *P. gingivalis* in untreated wastewater and evaluating their reduction through treatment processes, this study aims to bridge a significant knowledge gap in WBE. If successful, integrating oral bacteria surveillance into WBE frameworks could revolutionize how we monitor, predict, and mitigate oral health diseases at a population level. Public health agencies could use wastewater data to design targeted interventions, such as fluoridation programs, oral health education campaigns, or improved access to dental care in communities with high oral bacterial loads (Melbye and Armfield, 2013).

2.0 Materials and Methods

<u>Study site & temporal sampling</u>:

100 sewage samples were collected from Blucher Poole Wastewater Treatment Plant, a local wastewater treatment plant (WWTP) in Bloomington, Indiana. Blucher Poole has a flow of more than 4.5 million gallons per day and caters to the northern part of Monroe County. This treatment plant was selected to represent the majority of the Bloomington, Indiana, population and to observe bacterial shedding rates in wastewater. These samples were collected weekly starting from June 2023 to May 2025. A second local WWTP was selected, Dillman Road Wastewater Treatment Plant, so that we were able

111 to compare and contrast between the bacterial quantification of the two plants. Dillman
112 Road is located on the south side of Bloomington, Indiana and has a peak hydraulic
113 capacity at 30 million gallons daily (Bloomington, 2023). For this WWTP, 13 weekly
114 sewage samples from December 2023 to February 2024 were collected and transported
115 to the lab. 24-hour composite influent (prior to primary treatment) wastewater samples
116 were collected in 500-milliliter sterile polypropylene bottles and transported in a cooler
117 and frozen to -20°C within 2 hours of collection. Once received, these samples are
118 immediately prepared for filtration.

119 Effluent Sampling

120 Composite samples of primary and secondary/final effluent wastewater were collected
121 from the local WWTP and placed at -20°C for storage until sample processing. These
122 samples were collected during a 2-week intensive study and in the month of February
123 when concentrations were highest. For the primary influent, a 500 mL 24-hour
124 composite sample was collected, this is the sewage sample that comes directly into the
125 treatment plant and has not received any treatment. We received a 100 mL sample of
126 the 24-hour composite primary effluent sample, which consists of the sewage sample
127 after primary sedimentation has occurred. For the 24-hour composite secondary/final
128 effluent, 500 mL was collected in 500 mL sterile polypropylene bottles. This sample is
129 the sewage sample post aeration, activated sludge, and secondary sedimentation. All
130 samples were transported in the same manner as mentioned previously.

131

132 Decay Experiments:

133 A decay experiment was conducted on Streptococcus mutans in wastewater over the
134 course of a month to observe its persistence. The experiment was conducted in
135 triplicates of 400 milliliters of composite influent wastewater in 500-milliliter flasks.
136 Flasks were then covered with parafilm and left in the dark for a month. 25 mL samples
137 were taken at each of the following time points: 2 hours, 1 day, 4 days, 7 days, 11 days,
138 and 27 days. Before taking each sample, the flasks were swirled to homogenize the
139 wastewater and bacteria inside. Samples were then processed using the methods
140 below and quantified for *S. mutans*.

141 Concentration and DNA Extraction:

142 For final effluent samples, 250 mL of the final effluent was taken to be filtered and for all
143 other samples, 50 mL was prepared to be filtered. All samples were acidified to a pH of
144 3.5. A known concentration of bovine coronavirus solution was also added to each
145 sample as a tracer. For filtration, an electronegative mixed cellulose ester (MCE) 47mm
146 diameter and 0.45 µm pore size filter was used to filter samples based on previous
147 studies (Bivins et al., 2020b; Greaves et al., 2022; Rodriguez et al., 2024). Once
148 filtration through the filter was complete, the filters were then transferred into 2.0 mL
149 PowerBead tubes and either further extracted immediately or stored at -20 °C for
150 extraction later. The DNA from the samples was then extracted in accordance to the
151 provided manufacturer instructions using the Allprep PowerViral DNA/RNA extraction kit
152 (Cat. No. 28000-50 Qiagen, Germantown, MD,USA). This kit resulted in the elution of

153 DNA in 100 µL of RNase-free water provided within the kit. Once eluted these samples
154 were then stored at -20°C in preparation for quantification.

155 Bacterial and Viral Quantification:

156 Bacterial quantification of the samples was performed using digital polymerase chain
157 reaction (dPCR) and the QIAcuity™ Four Platform System (Cat. No 911042, Qiagen,
158 Germantown, MD, USA), the QIAcuity Nanoplate 26k (Cat. No 250001, Germantown,
159 MD, USA), and the QIAcuity™ Probe PCR Kit (Cat. No. 250132 Qiagen, Germantown,
160 MD, USA) as described in previous studies (Rodriguez et al., 2024). The environmental
161 mix for each molecular testing consisted of 1X Qiacuity Probe PCR mix, 08 µM of each
162 forward and reverse primer, 0.4 µM of each probe, and 10 µL of the target DNA for a
163 total volume of 40 µL. The molecular primers and probes used for the detection of *S.*
164 *mutans* and *P. gingivalis* are described in **Table S1**. While the primer and probe sets
165 were chosen from peer-reviewed, previously validated assays, their specificity was
166 formally assessed through in silico screening using NCBI BLAST. Primer and probe
167 sets were also able to detect a diluted culture of each bacteria. All samples were tested
168 using a duplex, where *S. mutans* was detected in the green channel with the FAM probe
169 and *P. gingivalis* was tested in the yellow channel with the HEX probe. The primers and
170 probes were manufactured by IDT (Coralville, IA, USA). The Zen™ internal quencher
171 (IDTDNA.com) and the 3' Black Hole ™ quencher were used to double-quench the
172 probes. PCR was run using the following conditions: an initial denaturation step at
173 95 °C for 2 minutes then 45 cycles of 95 °C for 5 seconds and 60 °C for 30 seconds.
174 The lowest detection limit was estimated for each PCR assay using DNA controls and a

175 dilution series which resulted in a calculated 380 copies/L for both *S. mutans* and *P.*
176 *gingivalis*. CrAssphage was used as a molecular fecal indicator and quantified with
177 techniques, probes, and primers published previously (Bivins et al., 2020a; Greaves et
178 al., 2020a; Wu et al., 2020) The threshold for each PCR reaction was marked by the
179 top of the negative band of the negative control for the specific probe being tested.

180 Data analysis and statistics:

181 The following formula was used to calculate the concentration of oral bacteria in gene
182 copes/L:

183 $$\frac{gc}{L} = \frac{gc}{uL} X \frac{Vol\ PCR\ reaction\ (40uL)}{Vol.\ NA\ analyzed\ (5uL)} X \frac{Vol.\ NA\ eluted\ (50uL)}{vol\ sample\ (0.05L)}$$

184 The analyses for our data was conducted using ANOVA and was performed on
185 GaphPad Prism v 10 (Boston, MA, USA) where independent factors were taken into
186 consideration. Graphs and figures were made using GraphPad Prism v 10 (Boston,
187 MA, USA). **For calculating the rate of decay, the decay curve was fit to the**
188 **following formula:**

189 $$C_T = C_0 e^{-kt}$$

190 In this equation, C_T represents the concentration of the pathogen at time *T*, C_0
191 represents the initial concentration of the pathogen at time 0, and *k* is representative of
192 the decay rate.

193

3.0 Results

Bacterial and Viral Detection and quantification:

Figure 1 shows the average monthly wastewater flow rates into the main local wastewater treatment plant tested in this study. Values throughout the year show the lowest value being in the summer and the highest values in the winter months. In addition to monitoring flow rates, the fecal indicators crAssphage was measured in all the samples throughout the duration of the experiments and concentrations remained stable over the two-year period (**Figure S1**). CrAssphage had an average detected concentration of 8.50 $\log_{10}$ GC/L. Statistical tests were done using a one-way ANOVA followed by tukey multiple comparisons to measure changes in monthly concentrations crAssphage, and results showed no statistical differences between crAssphage concentrations over the different months of the experiment.

Figure 1. Average wastewater flow rate per month for the local wastewater treatment plant monitored.

Figure 2 shows the monthly average concentrations over the span of two years for *S. mutans* and *P. gingivalis* in the main local wastewater treatment plant. Bacterial concentrations were normalized by wastewater flow rates to accommodate for population changes. The highest concentration of *S. mutans* was observed in February of year 1 with a calculated monthly average concentration of 5.01 $\log_{10}$ GC/L and the lowest detected concentration being in August of year 2 with 3.39 $\log_{10}$ GC/L. For *P. gingivalis*, the month with the highest average concentration was November 2023 with a calculated average monthly concentration of 3.81 $\log_{10}$ GC/L and the month with the lowest values was September 2024 where none of the samples had detections and the

218 values were assumed to be the detection limit. Over the course of the entire selected
219 timeline, the average detected concentration of *S. mutans* and *P. gingivalis* was 4.57
220 $\log_{10}$ GC/L and 3.03 $\log_{10}$ GC/L respectively. **Table 1** breaks down the concentration
221 values for *S. mutans* and *P. gingivalis* into four different time periods within the year,
222 corresponding with Spring (March-May), Summer (June-August), Fall (September-
223 November), and Winter (December-February). Values are also the average of the two
224 years. For *S. mutans* the highest average detected concentration was in the winter with
225 a value of 4.78 $\log_{10}$ GC/L and a positive detection rate of 100%. Statistical tests
226 showed winter concentrations were significantly higher than summer and spring
227 concentrations for *S. mutans*. *P. gingivalis* also had the highest average detected
228 concentration in the winter with a value of 3.12 $\log_{10}$ GC/L and a positive detection rate
229 of 84% which was also the highest detection rate across all seasons. No significant
230 differences were found between the concentrations across all seasons for *P. gingivalis*.

231 **Figure 2.** Concentrations of oral bacteria in wastewater. Top two figures show monthly
232 average concentrations of *S.mutans* (A) and *P. gingivalis* (B) in Bloomington
233 wastewater over the two-year duration normalized by wastewater flow. The bars are
234 standard deviation for four samples collected each month (n=4-5). Middle figures show
235 average concentrations for *S.mutans* (C) and *P. gingivalis* (D) in each season over the
236 two years. Bottom figures show violin plots for both oral bacteria in year 1 and year 2 (E
237 for *S.mutans* and F for *P. gingivalis*).
238

239

240

241

242

243

Table 1: Detection rates and average concentrations of *S. mutans* and *P. gingivalis* in wastewater samples.

Target	Seasons	Sample period	No. of Positive Samples (%)	Concentration (Log_{10} copies/L)
S. mutans	Spring 2024 & 2025	March-May	19 (76)	4.37
	Summer 2023 & 2024	June-August	20 (80)	4.34
	Fall 2023 & 2024	Sept-Oct	25 (100)	4.35
	Winter 2024 & 2025	Jan-Feb & Dec previous year	25 (100)	4.78
	Total		89 (89)	4.57
P. gingivalis	Spring 2024 & 2025	March-May	12 (48)	2.93
	Summer 2023 & 2024	June-August	12 (48)	2.75
	Fall 2023 & 2024	Sept-Oct	13 (52)	3.04
	Winter 2024 & 2025	Jan-Feb & Dec previous year	21 (84)	3.12
	Total		58 (58)	3.03

A comparison was also done between year 1 (June 2023 to May 2024) and year 2 (June 2024 to May 2025) through using Pearson's correlation r. Statistical analysis showed no correlation between the different years for both bacteria (**Figure S3**). Correlation analysis for crAssphage for the different years showed a strong positive correlation (r=0.77). A comparison was made between two different WWTP, Blucher Poole (BP) and Dillman Road (DR), for the two bacteria in the winter of year 2, which can be observed in **Figure S2**. For both WWTPs, *S. mutans* was observed to have a

256 larger spread in concentrations than *P. gingivalis* which can be observed in the top two
257 graphs within **Figure S2**. More samples of *P. gingvalis* were disregarded due to not
258 being detected, in comparison to *S. mutans*. For BP, the average concentration of *S.*
259 *mutans* was 4.93 $\log_{10}$ GC/L and for *P. gingivalis* it was 3.14 $\log_{10}$ GC/L. The average
260 concentration of *P. gingivalis* for DR was higher at 3.53 $\log_{10}$ GC/L whereas *S. mutans*
261 was relatively similar to BP with an average concentration of 4.86 $\log_{10}$ GC/L. *P.*
262 *gingivalis* was statistically higher in the DR WWTP compared to the BP WWTP whereas
263 there were no statistical differences between the concentrations of *S. mutans* in the DR
264 and BP WWTPs.
265 <u>Effluent sampling:</u>
266 In **Figure 3** the concentrations of *S. mutans* and *P. gingivalis* in primary influent, primary
267 effluent, and secondary effluent are shown. For both species of oral bacteria, they were
268 most prevalent in the primary influent samples with *S. mutans* having an average
269 concentration of 3.87 $\log_{10}$ GC/L and for *P. gingivalis*, a concentration of 3.21 $\log_{10}$
270 GC/L. The difference in concentration between the primary influent and the primary
271 effluent samples was larger for *P. gingivalis* than it was for *S. mutans* with calculated
272 differences of 1.08 $\log_{10}$ GC/L and 0.106 $\log_{10}$ GC/L, respectively. The final effluent
273 samples still resulted in some detected concentrations, with *S. mutans* having an
274 average of 3.08 $\log_{10}$ GC/L and *P. gingivalis* having an average of 1.99 $\log_{10}$ GC/L. The
275 difference between primary influent and secondary effluent for both *S. mutans* and *P.*
276 *gingivalis* was significant ($p<0.0001$). For *S. mutans*, the average concentration for
277 primary effluent and secondary effluent was determined to be significant as well
278 ($p<0.0001$). The difference between the concentration of *P. gingivalis* in primary influent

279 and primary effluent samples was significant (p=0.009). There was determined to be no
280 significance in the concentration of *S. mutans* in the primary influent and the primary
281 effluent samples (p=0.816) as well as there being no significant difference in the
282 concentration of *P. gingivalis* between the primary effluent and secondary effluent
283 samples (p=0.064).

284 **Figure 3.** Occurrence of *S. mutans* and *P. gingivalis* in wastewater treatment plant
285 primary influent, primary effluent, and secondary effluent in 4 replicate samples.
286

287 Decay Rate:

288 The decay rate of *S. mutans* at room temperature in the absence of sunlight was
289 observed over the span of one month, with a visual representation of the data being
290 shown in **Figure 4**. There was positive detection for *S. mutans* all the way up to 27
291 days with an average value of 4.05 $\log_{10}$ GC/L. Across all three replicates, the average
292 k_{obs} for *S. mutans* was -0.4786 d^{-1}. For *P. gingivalis*, the decay rate was unable to be
293 observed due to the low initial concentration of the bacteria in wastewater.

294 **Figure 4.** Decay of *S. mutans* in wastewater primary influent at room temperature in the
295 absence of sunlight.
296

297 **4.0 Discussion**

298 To the best of the authors' knowledge, this study is the first study to detect and
299 quantify *S. mutans* and *P. gingivalis* in wastewater samples. These two pathogens
300 cause two of the most common dental diseases that infect a majority of populations
301 worldwide. Even though these pathogens are highly prevalent in US populations,
302 routine surveillance on the prevalence of these different pathogens or the oral disease
303 they cause is not done, especially since the outbreak of the COVID-19 pandemic (Dani

304 et al., 2016; Yan et al., 2021). Through our study, we were able to show that both
305 pathogens were detected in more than 60% of the 65 samples tested in wastewater
306 over the 4 different seasons in a year. The high detection of these oral pathogens in
307 wastewater samples from a mid-size city (75,000 residents) shows that wastewater-
308 based epidemiology (WBE) is highly feasible for these dental pathogens and oral
309 health. WBE may also serve as a low-cost method to monitor the spread and
310 prevalence of these dental diseases when traditional monitoring methods are not done.
311 *S. mutans* had consistently higher concentrations than *P. gingivalis* in wastewater
312 throughout the sampling period. In some samples, concentrations of *S. mutans* reached
313 to more than 10 times higher than *P. gingivalis*. With numerous studies estimating
314 higher percentages of tooth decay (90%) than gum disease (50%) in adults (Research,
315 2022; United States. Public Health Service. Office of the Surgeon General and National
316 Institute of Dental and Craniofacial Research (U.S.), 2021), our differential observations
317 of *S. mutans* (which associates with tooth decay) and *P. gingivalis* (which associates
318 with gum disease) is consistent with past clinical prevalences of these diseases in US
319 populations (Griffen et al., 1998; Rafiei et al., 2018; Thorild et al., 2002; Zubaidah et al.,
320 2022). Higher prevalences of a disease should result in higher concentrations in
321 wastewater (Rabe et al., 2023; Weidhaas et al., 2021). However, concentrations of *S.*
322 *mutans* could also be higher in wastewater due to the shedding dynamics from teeth as
323 opposed to the shedding dynamics of *P. gingivalis* from gums (Bugueno et al., 2020;
324 Liao et al., 2014; Liu et al., 2017). While studies have not specifically tested shedding of
325 each pathogen, previous studies have observed statistically higher concentrations of *S.*
326 *mutans* than *P. gingivalis* in dental samples from healthy patients, alluding to higher

327 shedding of *S. mutans* than *P. gingivalis* (Almeida et al., 2020; Dani et al., 2016; Davis
328 et al., 2012). Differential shedding could be due to the stark difference in oral hygiene
329 when it comes to the gums and teeth where cleaning of the teeth is done more
330 frequently than cleaning of the gums (Albertsson and Dijken, 2010; Deinzer et al., 2019;
331 Goryawala et al., 2016; Zimmermann et al., 2015). The variations in shedding might
332 also be simply attributed to the ease with which they attach or detach from different
333 surfaces, such as enamel versus gums (Gibbons, 1984; Mei et al., 2009; Vanhoute,
334 1983).

335 In addition to being shed in saliva, oral pathogens may also be swallowed, survive
336 passage through the gastrointestinal tract, and be excreted in feces. Several studies
337 have detected the DNA of oral microbes, including S. mutans, in human feces,
338 particularly through 16S rRNA gene sequencing (Abdelbary et al., 2022; Lin et al.,
339 2024). This fecal shedding pathway may significantly influence the concentration of
340 these bacteria in wastewater. For example, *S. mutans* may be more resilient than *P.*
341 *gingivalis* during gastrointestinal transit, potentially resulting in higher levels of S.
342 mutans in fecal matter. While feces are generally considered the primary route of
343 microbial contribution to wastewater, no dedicated studies have confirmed the specific
344 shedding patterns of *S. mutans* and *P. gingivalis* (Newton et al., 2015). As a result,
345 there remains uncertainty about how their wastewater concentrations correlate with
346 actual infection prevalence in the population. Future studies should examine the
347 shedding dynamics of each oral pathogen so that improved connections between dental
348 health and wastewater concentrations can be developed.
349

350 Seasonal Patterns

351 WBE has been shown to be a very useful tool for understanding disease trends,
352 specifically over the different seasons of a year (Brinkman et al., 2017; Kuhn et al.,
353 2023). When trends for different seasons are determined, health agencies can then pick
354 specific seasons throughout the year to focus mitigation efforts on (dos Santos et al.,
355 2024; Mao et al., 2020). Our results showed seasonal trends for *S. mutans* and *P.*
356 *gingivalis,* with both oral bacteria having their highest average concentrations in the
357 winters over the two-year period. However, results for *P. gingivalis* were not significant,
358 potentially due to the low detection rate of this pathogen. Nevertheless, detections in
359 winter for *P. gingivalis* were also much higher than the detections in other months,
360 suggesting potential seasonality similar to *S. mutans*.

361 *S. mutans* showed significantly higher concentrations in the winter than in the
362 spring and summer. The highest temperature months of July and August exhibited
363 notably lower concentrations compared to the other months of the year, especially in
364 year 2. These results highlight that *S. mutans* and dental caries could be more prevalent
365 in months with colder weather. Prior studies have observed diminished oral health in
366 colder months due to drier mouths and immune system changes in the winter (Fares,
367 2013; Fisman, 2007). Drier mouths due to increased indoor heater use can reduce the
368 volume of saliva (known to prevent bacterial growth), which in turn can cause the
369 extended growth of pathogens like *S. mutans* (King et al., 2000; Ligtenberg et al., 2020;
370 Weng et al., 2022). Colder months can also lead to diet changes, lowering nutrient
371 levels, or less hydration which could potentially contribute to tooth decay and poorer
372 oral health in colder months compared to hotter months (Fares, 2013; Moynihan and

373 Petersen, 2004; Sheiham, 2001). Although we observed higher average concentrations
374 of oral pathogens during the winter months across both years, several outlier months in
375 each season deviated from this trend, suggesting that additional factors may be
376 influencing oral health dynamics. These findings are also region-specific; other areas
377 may exhibit different seasonal patterns for these two oral pathogens. Future studies
378 should integrate oral health indicators with behavioral and environmental factors to
379 uncover the underlying drivers of seasonal variation.

380 Though average concentrations in the different seasons across years show
381 potential seasonal trends, trends of bacteria in each year were not well correlated
382 (**Figure S3**). Specifically for S. mutans, our data observed significantly lower
383 concentrations in year 2 than in year 1 suggesting reduction in oral pathogen burden in
384 the community. P. gingivalis has statistically similar concentrations across both years
385 but concentrations over time were also not well correlated. A potential reason for
386 reduction in oral health burden is that COVID-19-related dental clinic closures and
387 delayed care likely worsened oral health, but as services resumed, individual dental
388 health may have improved, potentially lowering oral health-related markers in
389 wastewater over time (Brian and Weintraub, 2020; Dill et al., 2023). Prior clinical
390 studies have also showed lowering oral health burden over the past decade which
391 follow the trend in our study (Dai et al., 2025; Lagerweij and van Loveren, 2015; Qin et
392 al., 2022). Additionally, year to year patterns can significantly change depending on
393 healthcare access, economic conditions, and public health policies that affect
394 community oral health in a year (Cooray et al., 2025; Dunleavy et al., 2024; Lee et al.,
395 2021).

396 Variation in WWTP

397 Our study results showed that *S. mutans* concentrations in wastewater from both
398 WWTP's were not statistically different within the wintertime even though both WWTPs
399 serve different population numbers and types. These results suggest that *S. mutans* can
400 be prevalent in different WWTP and populations across geographical areas. The higher
401 observed concentration of *S. mutans* compared to *P. gingivalis* in the DP WWTP is
402 consistent with what was observed for BR WWTP. Our results do show statistically
403 higher concentrations of *P. gingivalis* in the DR WWTP compared to the BP WWTP
404 ($p=0.0273$). BP WWTP primarily serves the university campus community, which is
405 mostly comprised of young students between the ages of 18 and 24. DR WWTP serves
406 the rest of the local population which contains children and vulnerable groups that may
407 not be present in the other WWTP. As oral health significantly impacts those that are
408 most vulnerable, such as children (below 18) and elderly (above 65), it is expected that
409 there would be higher levels of reduced oral health in the DR WWTP which contains
410 these vulnerable groups (Bloomington, 2023; Weng et al., 2022; Xiao et al., 2020).
411 However, to specifically determine whether these factors affect oral health, further
412 analysis is needed on samples across the sewershed and in other geographic locations.

413 Fate in the wastewater treatment process

414 Throughout the wastewater treatment process, both *S. mutans* and *P. gingivalis*
415 were detectable but at significantly lower concentrations. These data suggest that the
416 treatment process is reducing the oral bacterial population, but not completely. The
417 primary treatment step was able to significantly reduce *P. gingivalis* but the secondary
418 treatment step (both activated sludge and secondary sedimentation process) was

needed to reduce *S. mutans*. These differences are potentially due to how likely each microbe is to stick to fecal particles in wastewater. Multiple prior studies have shown a reduction of various pathogens in wastewater through the primary and secondary treatment processes (Delanka-Pedige et al., 2020; Frigon et al., 2013; Fu et al., 2010; Skouteris et al., 2020). The same studies also show that certain pathogens are able to survive through the process and enter the environment at lower levels, similar to what we are observing for *P. gingivalis* and *S. mutans* (Delanka-Pedige et al., 2020; Frigon et al., 2013; Fu et al., 2010; Skouteris et al., 2020) (Cuevas-Ferrando et al., 2022). Beyond assessing the fate of oral bacteria in the wastewater treatment plant, our study assessed the decay of oral bacteria in wastewater. With *P. gingivalis* having very low concentrations, assessing its decay in water would be difficult. Furthermore, as *P. gingivalis* is an anaerobic bacteria, its persistence in wastewater would be lower than *S. mutans* due to the presence of oxygen in wastewater (Diaz and Rogers, 2004; Lemos et al., 2019; Rafiei et al., 2018; Skouteris et al., 2020). Our calculated decay rates (0.48 d^{-1}) for *S. mutans* in wastewater are comparable with other types of common fecal bacteria found in wastewater and the environment, such as E. coli (-0.14 to -1.13 day^{-1}) (Chan et al., 2015; Nakhle et al., 2021; Tiwari et al., 2023) and enterococci (-0.19 to -1.2 day^{-1})(Greaves et al., 2020b; Sagarduy et al., 2019; Tiwari et al., 2019; Tiwari et al., 2023). This environmental and wastewater treatment plant survival, therefore, highlight the potential novel transmission pathway of these oral pathogens through the environment in contaminated waters.

<u>Limitations</u>

441 A key limitation of our study is the inability to compare our wastewater data with clinical
442 diseases that these pathogens cause (periodontal diseases and dental caries). The
443 main reason why we cannot access this data is because there is no clinical surveillance
444 of these pathogens in our region which highlights how important wastewater
445 surveillance can be to the monitoring of oral health. Future studies should try to
446 incorporate clinical studies or survey data with wastewater surveillance to better
447 connect wastewater data with the oral health of the community. Another major limitation
448 includes the use of only molecular methods to detect the various oral pathogens in this
449 study. While molecular methods offer fast and precise measurements for a diverse
450 range of targets, they do not assess viability of specific organism. Subsequent studies
451 should incorporate culturable or other viability assessment methods to measure the
452 viable concentration of oral pathogens, especially when investigating persistence.

453 **5.0 Conclusion**

454 In conclusion, this study demonstrated the feasibility of using WBE for oral pathogen
455 surveillance in a community. Additionally, our study showed a potential environmental
456 transmission pathway for *S. mutans* through water. Overall, this research has the
457 potential to provide critical insights into oral health trends, improve disease surveillance,
458 and enhance public health strategies. By leveraging wastewater analysis, we can move
459 toward a more proactive and non-invasive approach to oral disease monitoring,
460 ultimately contributing to better health outcomes and reducing the global burden of
461 dental and periodontal diseases.
