Abstract:

This study evaluated the presence of HPV DNA in the cervix and peripheral blood of women with cervical intraepithelial neoplasia (CIN I, II, and III) and healthy individuals. Overall, 139 paired peripheral blood and cervix samples of healthy women and women with CIN I, II, and III (n= 68) were tested for HPV DNA by using standard procedures. PCR-sequencing determined HPV types. Quantification of HPV16 E6 and E2 genes was performed to determine viral load and physical state. HPV DNA was detected in the cervix (21.1% in healthy individuals; 48.8-55.5% in CIN patients), blood (46.4% in healthy individuals; 44.1-77.7% in CIN patients), and paired peripheral blood and cervix samples (24% in healthy individuals; 32.5-44.4% in CIN patients). The most frequent types found in the cervix were HPV16, 18, 31, 33, 58, and 70, while HPV16, 18, 33, 58, and 66 were the most frequent types found in the blood. HPV DNA in the cervix was associated with previous sexually transmitted infections (STIs) (P=0.023; OR: 2.978; CI:1.34-7.821), HPV DNA in the blood (P=0.000; OR: 8.283; CI:3.700-18.540), and cervical lesions (CIN I/II or III) (P=0.007). Binomial logistic regression showed that HPV DNA in the blood (P=0.000; OR: 9.324; CI:3.612-24.072) and cervical lesions (P=0.011; OR: 3.622; CI:1.338-9.806) were associated with HPV DNA in the cervix. However, we did not find an association between HPV DNA in the blood and cervical lesions (P=0.385). Our results showed that only HPV DNA found in the cervix was associated with cervical lesions.

Keywords: HPV DNA; Cervix; Peripheral Blood; Cervical lesions; Healthy individuals.

1. Introduction

Cervical cancer is the fourth most common malignancy diagnosed in women worldwide, accounting for 6.6% of total cancer cases [1]. Nearly 90% of deaths caused by cervical cancer occur in women from middle and low-income countries [1].

It is well established that persistent infection caused by Human Papillomaviruses (HPV) is involved in cervical and head, and neck carcinogenesis [2–9]. Despite the advances in vaccination, treatment, and monitoring, cervical cancer is still a significant cause of death in middle and low-income developing countries [1]. Hence, there is a need for minimally invasive biomarkers to monitor cervical cancer and cervical lesions. Recent studies have shown that circulating free DNA (cfDNA) or circulating tumor DNA (ctDNA) may be valuable tools for monitoring cancers caused by HPV [10–16]. In this scenario, several studies have demonstrated the presence of HPV DNA in peripheral blood mononuclear cells [17–25], serum [26,27], and plasma [28–30] from cervical cancer and non-cervical cancer patients. However, despite its importance, few studies evaluate the HPV DNA in paired peripheral blood and HPV DNA in the cervix from precancerous cervical patients and healthy individuals [21–24,30–32]. Thus, this study evaluated the prevalence of HPV DNA and viral load in paired peripheral blood and cervix samples in cervical intraepithelial neoplasia (CIN I, II, and III) patients and healthy individuals.

2. Materials and Methods

2.1. Patients

The paired cervix and blood samples were obtained from women during their gynecological consultation at Hospital das Clínicas, Pernambuco State, Northeast Brazil. The samples were collected from November 2010 to December 2016. A total of 139 women agreed and signed free and informed consent forms. This study was approved by

the Ethics and Research Committee (CAAE: 0058.0.106.000-10, HUOC/PROCAPE 64/2010) and (CEP/CCS/UFPE under CAAE: 09307612.8.0000.5208). In this study, we examined 139 paired cervix and blood samples. Among these, 71 (51%) were healthy individuals, 43 (31%) patients with cervical intraep-ithelial cervical grade I (CIN I), 16 (11.5%) patients with cervical intraepithelial cervical grade II (CIN II) and 9 (6.5%) patients with cervical intraepithelial cervical grade III (CIN III). Cervical cancer samples (paired cervix and blood samples) were excluded due to possible metastasis processes.

2.2.HPV DNA cervix and blood samples

DNA from cervical and peripheral blood was extracted using the DNeasy Blood & Tissue Kit (QIAGEN GmbH, Hilden, Germany), following the manufacturer's instructions. Subsequently, all samples were quantified using a spectrophotometer (NanoVue Plus Spectrophotometer). DNA quality was confirmed by polymerase chain reaction (PCR), which amplifies a fragment of the β-globin gene with the primers described in **Table 1**.

The presence of HPV DNA was assessed by amplification with two sets of oligonucleotides. The first step was performed with the set of consensus and degenerate primers MY09/11 (Table 1), which anneal in a conserved region of the L1 gene, amplifying a product of approximately 450 bp. Subsequently, nested-PCR was performed using oligonucleotides GP05/06, generating a fragment of approximately 140 bp. The cloned HPV 16 genome and HPV-positive cervical cancer samples were used as positive controls in all PCR reactions. Besides, all tests were performed in triplicate.

HPV-positive samples were genotyped by PCR/sequencing. PCR products were sequenced by the dideoxy-terminal fluorescent method by using the ABI PRISM BigDyeTM Terminator Cycle Sequencing v 3.1 Ready Reaction kit (Applied Biosystems,

USA). The sequences were analyzed using the Staden package (STADEN, 1996), with the programs Gap4 (version 4.0) and Pregap4 (version 1.5), which were used to assembly the contigs of the sequences obtained from HPV DNA. After the contig assembly, the BLAST program, available at http://blast.ncbi.nlm.nih.gov/Blast.cgi, was used to compare previously known HPV sequences.

2.3. Viral load and physical status

Real-time PCR (qPCR) was used to determine the viral load and physical status of HPV 16 positive patients. For this, seven random paired cervix and blood samples derived from CIN I, II, and III and 12 patients with normal cervical cytology were selected. HPV16 viral load was determined through E6 gene levels present in all patient groups. Each sample's viral load was expressed as the number of copies of E6 in 50 ng of DNA [33]. A series of dilutions of the complete HPV genome cloned into the pBR-322 vector was carried out to generate the standard curve. Calibration curves for the E2 and E6 genes were created by using the standard dilutions. The DNA extracted from CaSki and SiHa cell lineages was used as a positive control for the reactions. Once calibration curves were constructed for each gene, the samples were analyzed in duplicate. As for physical status, the virus was considered integrated into the host genome when the E2 gene was not detected. E2/E6 ratio was calculated to differentiate the episomal from the mixed physical status. E2/E6 ratio < 1 indicates the mixed physical status; values > 1 indicate the predominance of the episomal physical status [33].

2.4. Statistical analysis

Clinical aspects of patients were compared between patients with HPV DNA positive and negative in the cervix by using chi-square and Fisher's exact tests. We

performed hierarchical binary logistic regression analysis to identify the variables associated with HPV positive in the cervix, HPV DNA in blood, and cervical lesions. The correlation of viral load of HPV16 DNA in paired cervical and blood samples was examined using the Pearson correlation coefficient test. All P-values were two-sided with a significance level of 0.05, except the Pearson correlation. All data were analyzed using SPSS version 26 (SPSS Inc.Illinois, USA).

3. Results

3.1.HPV DNA detection in cervix and blood samples

Regarding the cervix or peripheral blood samples, HPV DNA was detected in 50.7% of healthy individuals, 60% in CIN I, 75% in CIN II, and 88.8% in CIN III patients. In contrast, HPV DNA in the cervix was detected in 21.1% of healthy individuals, 48.8% in CIN I, 56% in CIN II, and 55.5% in CIN III patients. In peripheral blood, HPV DNA was found in 46.4% of healthy individuals, 44.1% in CIN I, 50% in CIN II, and 77.7% in CIN III patients. In paired cervix and peripheral blood samples, HPV DNA was found in 24% of healthy individuals, 32.5% in CIN I, 38% in CIN II, and 44% in CIN III patients (**Figure 1**).

The most frequently found genotypes in the cervix were HPV16, 18, 31, 33, 58, and 70, while HPV16, 18, 33, 58, and 66 were the most frequently found blood sample types. Globally, the genotypes most frequently found were HPV16 and HPV58 in both cervix and peripheral blood samples. Also, HPV16 was the most frequent genotype in the paired cervix and blood samples **(Figure 2)**.

HPV DNA in cervix were associated with previous STIs (P=0.023; OR: 2.978; CI:1.34-7.821), HPV DNA in blood (P=0.000; OR: 3.369; CI:3.700-18.540) and cervical lesions (P=0.007) **(Table 2)**. Binomial Logistic regression showed that HPV DNA in the

blood (P=0.000; OR: 9.324; CI:3.612-24.072) and cervical lesions (P=0.011; OR: 3.622; CI:1.338-9.806) were associated with HPV DNA in the cervix (**Table 3**). In contrast, only HPV DNA in the cervix (P=0.011; OR: 3.918; CI:1.366-11.239) was associated with HPV DNA in the blood (P=0.00), i.e., we did not observe an association between HPV DNA in blood and cervical lesions (P=0.385) (**Tables 4 and 5**).

3.2.Evaluation of viral load in paired cervix/blood tissues

According to the genotyping results, HPV16 was the best candidate to examine the viral load in the paired cervix and peripheral blood samples. Cervix and peripheral blood samples from 12 patients with CIN I, II, and III, and 17 healthy individuals were selected for viral load quantification. Regarding the CIN patients, the viral load varied from 3.65 to 21.58 (E6 copies/cell) in blood and 0.2 to 138 (E6 copies/cell) in the cervix. A correlation was observed between HPV16 viral load present in the cervix and peripheral blood samples in patients with CIN II/III (r=0.65) and CIN III (r=0.60) **(Figure 3)**.

It was also not observed integrated physical status in the blood samples from CIN patients. A positive correlation between HPV DNA viral load in cervix and blood was also observed in samples from women with the integrated or mixed virus in the cervix (r=0.64) and in mixed in their peripheral blood (r=0.66) **(Figure 4)**.

Regarding the healthy individuals, the viral load varied from 2.76 to 83.89 (E6 copies/cell) in blood and 0.12 to 246 (E6 copies/cell) in the cervix. The integrated, episomal, and mixed physical status were observed in peripheral blood and cervix samples. However, there was no correlation between HPV DNA viral load in the cervix and peripheral blood samples in healthy patients.

4. Discussion

This study investigated the presence of HPV DNA in paired peripheral blood and cervix samples from women with cervical lesions and healthy individuals. Our results showed HPV DNA in the cervix and peripheral blood samples of both healthy individuals and CIN patients. In addition, we also observed a significant association between the HPV DNA in the cervix and cervical lesions. However, we did not observe an association between HPV DNA in blood and cervical lesions. Besides, we found a positive correlation between HPV16 viral load in the paired cervix and blood samples in women according to CIN grade and physical status of the virus in the cervix and blood. Globally, our results showed the presence of HPV DNA in the cervix and peripheral blood from cervical lesions patients and healthy individuals. However, only HPV DNA found in the cervix was associated with cervical lesions.

Several studies have demonstrated the presence of HPV DNA in peripheral blood mononuclear cells [17–25], serum [26,27], and plasma [28–30] from cervical cancer and non-cervical cancer patients [17–25,27–31,34–36]. According to these studies, the prevalence of HPV DNA in blood ranged from 6.9% to 87%. The studied population, type of lesion, the methodology used to detect HPV DNA, and the specimen type (serum, plasma, and peripheral blood) may reflect the HPV DNA prevalence variation in peripheral blood. Our study found a high prevalence of HPV DNA in the blood of patients with cervical lesions from Northeastern Brazil, where diseases caused by HPV are a significant public health concern. HPV16 and HPV58 were the most frequent genotypes found in the cervix and blood of patients. We used PCR-sequencing to detect HPV DNA in whole peripheral blood and HPV DNA in the cervix. Although PCR-sequencing failed to detect multiple HPV types, this methodology is suitable for HPV DNA detection.

In this study, we also observed a direct relationship between the increase of prevalence of HPV DNA in blood and the severity of the lesions in patients with CIN I

(44.1%), II (50%), and III (77.7%). Similar results were observed in previous studies regarding patients with cervical lesions [28,30]. Furthermore, we observed a positive correlation between the HPV16 viral load in the paired cervix and blood samples, according to the severity of the lesions (r=0.65, CIN II/III; R=0.6, CIN III). In this context, a positive correlation between HPV DNA in blood with the severity or tumor size was also observed in cervical [11,17,27,38–40], head and neck [41–43], lung [20], and breast cancers [44], although a study has failed in finding similar results [30]. Thus, studies regarding HPV DNA viral load in patients with cervical lesions are needed since this methodology could be used for monitoring cervical lesions.

To date, few studies discuss the presence of HPV DNA in the blood of healthy subjects [22,24,32]. HPV DNA has also been detected in pediatric patients [22,37], healthy blood donors [22,23,32], and normal smears [25,30]. Here, we observed HPV DNA in 24% of the paired cervix and blood samples from non-cervical lesion patients. When put together, these findings confirm the presence of HPV in blood from subjects with no cervical HPV infection history. However, it is impossible to exclude that the high HPV DNA prevalence in healthy individuals is due to HPV infection in other body sites.

One of the HPV-induced process's key events is integrating the virus's genome into the host's genome [45]. The state of integration is fundamental for the initiation of viral replication. One clue that HPV DNA is integrated into the host genome is the loss of E2. Therefore, absolute quantification of the E2 gene was performed, aiming to determine the viral genome's physical status in peripheral blood samples from patients with cervical lesions and healthy individuals. Both groups presented predominance of the mixed form. How-ever, previous studies have reported a predominance for integrated [39] and episomal forms [22]. The virus's presence in mixed form and a high viral load in

healthy individu-als reinforces the hypothesis that the blood cells carry the virus. Further studies are needed to clarify this aspect.

HPV DNA in peripheral blood has been historically detected in cervical cancer and non-cervical cancer tumors, in which ctHPVDNA migrates from local infection to blood [22]. Furthermore, recent studies have shown cfHPVDNA in the blood of cervical cancer patients [10,27,46]. HPV DNA in the blood of patients with cancer can be originated through apoptosis, necrosis, nucleosomes, phagocytosis, extracellular vesicles, HPV carrier cells, and a combination of these mechanisms [47]. However, the dissemination of HPV DNA from cervical lesions and normal smear still needs to be understood. Our study found HPV DNA in peripheral blood from both patients with and without cervical lesions. In addition, we did not observe an association between HPV DNA in blood and cervical lesions. However, we found an association between HPV DNA in the cervix and cervical lesions. HPV DNA in blood could result from infections in other body sites, such as the head and neck. Hence, we speculated that the virus causes lesions that induce immune responses, predominantly lymphocytic, and then the cells would carry HPV DNA through the hematogenous route. In this scenario, studies focusing on Bovine papillomavirus (BPV) cattle infected, a model for HPV infection study, support this hypothesis. These studies demonstrated BPV DNA in cattle's peripheral blood with or without warts [48-58] and viral activity in lymphocytes [53, 55, 57]. Previous studies have suggested that the blood can be a viral reservoir for BPV [48, 53-58]. Studies in humans also support this hypothesis. For instance, some works have demonstrated HPV DNA in lymphocytes, dendritic cells, NK cells, neutrophils, B lymphocytes CD20+, and CD56+ [23,24].

In conclusion, we detected HPV DNA in the cervix and peripheral blood from cervical lesions patients and healthy individuals. However, only HPV DNA found in the

cervix was associated with cervical lesions. More studies are needed to clarify the role of HPV DNA in blood and tumorigenesis.

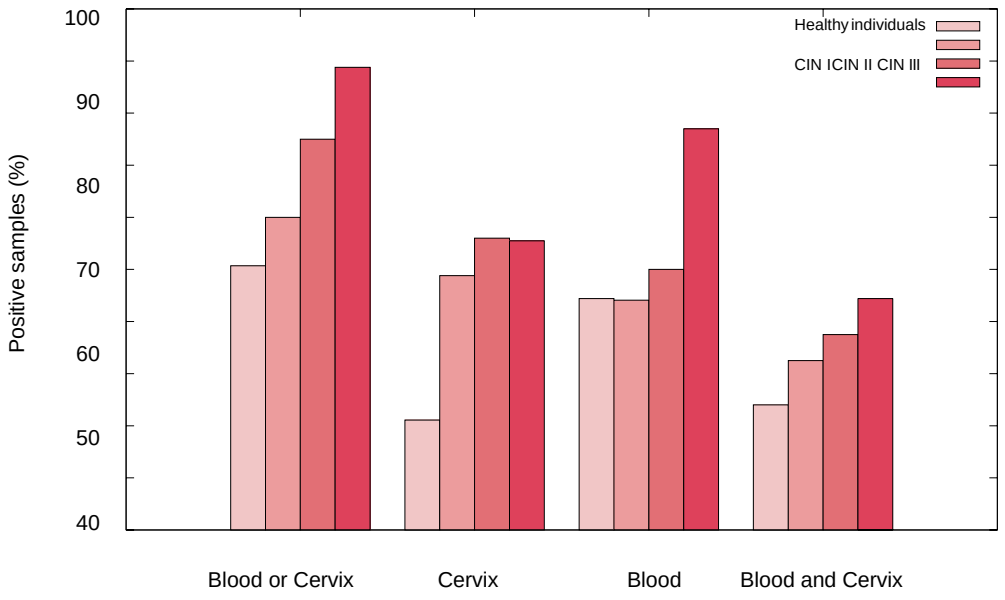

Figure 1. Prevalence of HPV in healthy individuals and CIN patients.

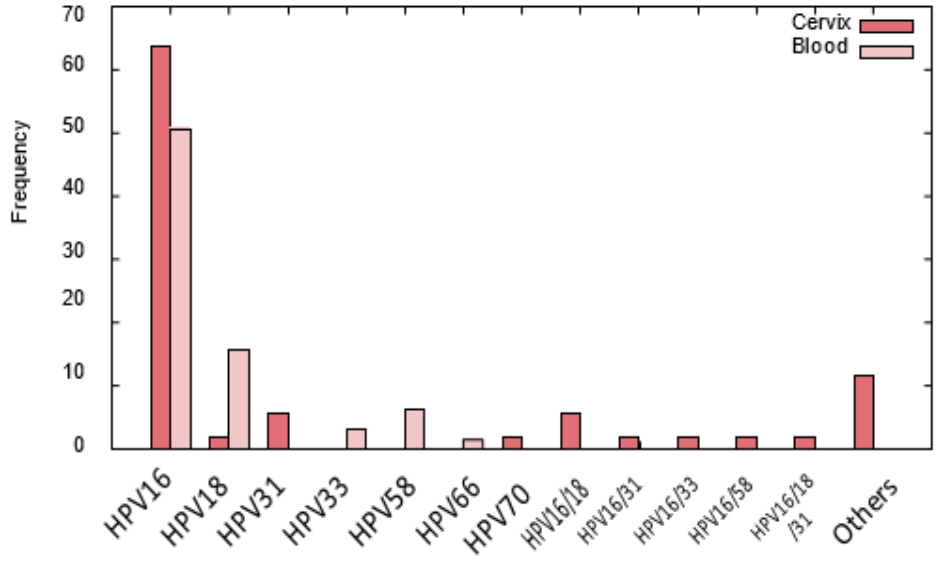

Figure 2. Frequency of HPV types found in the cervix and peripheral blood from women of Northeastern Brazil.

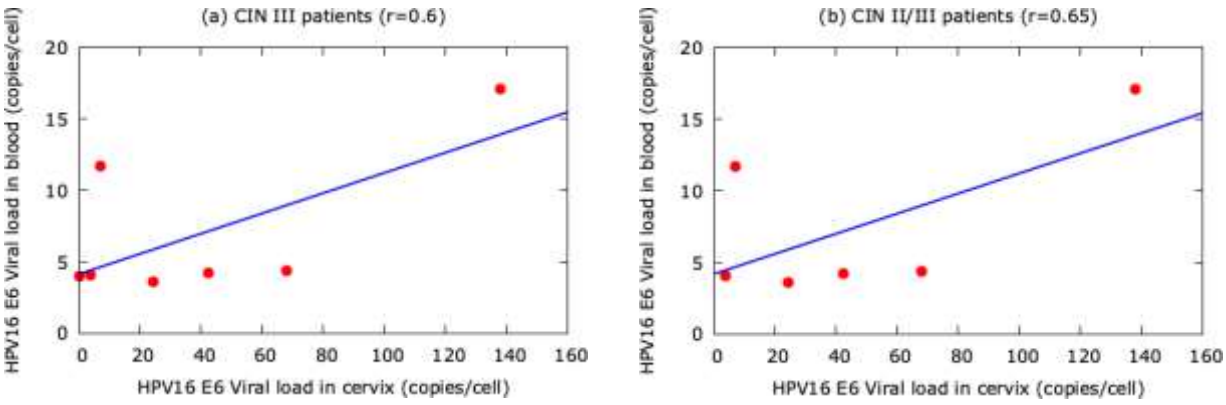

Figure 3. Correlation of HPV16 viral load between the cervix and peripheral blood samples. a - Positive correlation of HPV16 viral load between the cervix and peripheral blood samples in CIN III (r=0.6). b- Positive correlation of HPV16 viral load between the cervix and peripheral blood samples in CIN II/III patients (r=0.65).

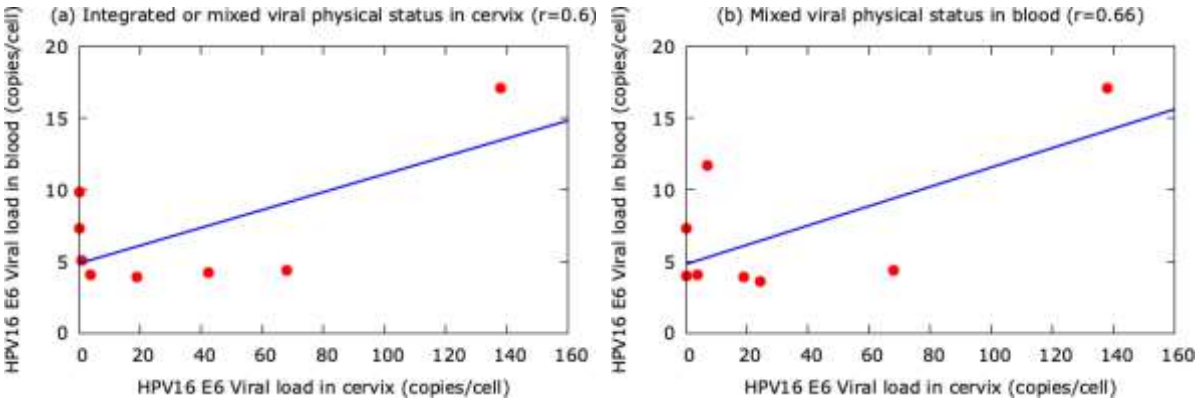

Figure 4. Correlation of HPV16 viral load between the cervix and peripheral blood samples ac-cording to viral physical status. A - Positive correlation of HPV16 viral load between the cervix and peripheral blood samples in women with integrated or mixed viral physical status in cervix (r=0.64). B - Positive correlation of HPV16 viral load between the cervix and peripheral blood samples in women with mixed viral physical status in peripheral blood (r=0.66).

Table 1. Primers used for PCR amplification, sequencing, and viral load analysis.

Primer	**Sequence (5'→3')**	**Size (bp)**
β-globina PC04 GH20	 ACACAACTGTGTTCACTAGC CAACTTCATCCACGTTCACC	110 bp
MY09 MY11	CGTCCMARRGGAWACTGATC GCMCAGGGWCATAAYAATGG	450 bp
GP5 GP6	TTTGTTACTGTGGTAGATAC GAAAAATAAACTGTAAATCA	110 bp
E6 HPV-16 Forward Reverse	 GAGAAACTGCAATGTTTCAGGACC TGTATAGTTGTTTGCAGCTCTGTGC	81 bp
E2 HPV-16 Forward Reverse	 AACGAAGTATCCTCTCCTGAAATTATT AG CCAAGGCGACGGCTTTG	76 bp

Table 2. Clinical and histological characteristics of patients according to HPV status in the cervix.
