Introduction

Croup (viral laryngotracheitis) is a common childhood upper respiratory disease, usually associated with parainfluenza or other endemic viruses, including seasonal coronavirus.[1] The infection results in varying degrees of inspiratory stridor, hoarse voice, barky cough, and respiratory distress up to and including complete airway obstruction. Sporadic case reports have suggested an association between SARS-CoV-2 and croup.[2-9] *Ex vivo* studies suggest that the Omicron variant (B.1.1.529) of SARS-CoV-2 replicates more rapidly in higher airways than previous lineages, suggesting the possibility of an increased risk for croup.[10] Here we merge epidemiologic and clinical data to evaluate whether there is indeed a high rate of croup as a manifestation of COVID-19, specifically with the Omicron variant.

Methods

High-level data was retrospectively extracted from patient charts among those seen in the Emergency Department (ED) at Seattle Children's Hospital, an academic, quaternary-care hospital with more than 50,000 annual ED visits prior to the COVID-19 pandemic. Inclusion criteria were patients who were assigned a diagnosis containing the word "croup" during either 5/30/2021-11/30/2021, a time period correlating with predominance of the SARS-CoV-2 Delta variant (B.1.617.2), or during 12/1/2021-1/15/2022, corresponding to the initial phase of the Omicron variant surge.

Qualitative SARS-CoV-2 polymerase chain reaction (PCR) testing from nasopharyngeal or mid-turbinate swabs were obtained at the discretion of the treating clinician, as were interventions including racemic epinephrine and hospitalization. Contemporaneous publicly available local data on the proportion of SARS-CoV-2 samples in surrounding King County, Washington, with spike gene target failure on TaqPath PCR assays was used as a proxy for the proportion of infections caused by the Delta and Omicron SARS-CoV-2 variants (https://depts.washington.edu/labmed/covid19/#sequencing-information). This study was approved by the Seattle Children's Hospital Institutional Review Board.

Results

A total of 401 patients were diagnosed with croup during the Delta surge and 107 patients were diagnosed with croup during the Omicron surge. Patients with croup who presented during the Omicron surge were more likely to test positive for COVID-19 (48.2% vs 2.8%, $p < 0.0001$, odds ratio 31.8) (**Table 1**). The rate of viral respiratory testing remained similar during both time periods. Children with a clinical diagnosis of croup during the Omicron surge were more likely to be administered racemic epinephrine as part of their care (21.5% vs 13.0%, $p = 0.032$). There were no differences in presenting age, rate of admission, rate of return to the ED within 72 hours, or admission among those who returned within 72 hours.

Using the local community prevalence of spike gene target failure as a proxy for the Omicron variant, the incidence of croup double compared to the rate in prior months, while at the same time the number of cases of parainfluenza virus identified decreased (**Figure 1**).

Discussion

We have identified a sharp rise in cases of croup seen in our pediatric ED in parallel with the replacement of the SARS-CoV-2 Delta variant by Omicron as the dominant variant in our community. This increase was not temporally associated with the circulation of parainfluenza virus, and indeed Omicron replaced parainfluenza as the predominant virus associated with croup during this time. Viral testing is not routinely recommended for patients with croup; testing that was performed was for a wide variety of patients and indications, but we do believe our data is a reasonable proxy for local population prevalence. The end of the study period coincided with a decrease in hospital testing capacity and thus we were not able to see if this trend continued with as much precision.

Croup patients during the Omicron surge were more likely to receive racemic epinephrine, suggesting a more severe initial clinical presentation. Based on admission rates and return visits, there is not enough data to alter current management after ED discharge.

Croup is one of the most severe manifestations of upper respiratory infections in children. As a common reason for ED visits, croup places a significant resource burden on health care systems. It appropriately generates tremendous fear and anxiety among children and their caretakers. As has been seen repeatedly during the COVID-19 pandemic, the protean clinical manifestations of SARS-CoV-2 have frequently humbled health care providers, with croup now needing to be

recognized as a common presentation of the Omicron variant, and possibly future variants as well.

Acknowledgments: We thank Pavitra Roychoudhury, PhD, Department of Laboratory Medicine and Pathology, University of Washington, for her help in accessing local SARS-CoV-2 surveillance data.
