Abstract

Introduction: Clear cell renal cell carcinoma extending into the inferior vena cava (ccRCC^{IVC}) represents a clinical high-risk setting. However, there is substantial heterogeneity within this patient subgroup regarding survival outcomes. Previously, members of our group developed a microRNA(miR)-based risk classifier – containing miR-21, miR-126 and miR-221 expression – which significantly predicted cancer-specific survival (CSS) of ccRCC^{IVC} patients.

Methods: Examining a single-center cohort of tumor tissue from *n* = 56 patients with ccRCC^{IVC}, we measured expression levels of miR-21, miR-126 and miR-221 by qRT-PCR. Prognostic impact of clinicopathological parameters and miR expression were investigated via univariate and multivariate cox regression. Referring to the previously established risk classifier, we performed Kaplan Meier analyses for single miR expression levels and the combined risk classifier. Cut-off values and weights within the risk classifier were taken from the previous study.

Results: miR-21 and miR-126 expression were significantly associated with lymphonodal status at time of surgery, development of metastasis during follow-up, and cancer-related death. In Kaplan Meier analyses, miR-21 and miR-126 significantly impacted CSS in our cohort. Moreover, applying the miR-based risk classifier significantly stratified ccRCC^{IVC} according to CSS.

Conclusion: In our retrospective analysis, we successfully validated the miR-based risk classifier within an independent ccRCC^{IVC} cohort.

1. Introduction

In about 10 % of all cases, clear cell renal cell carcinomas (ccRCC) extend into the inferior vena cava (ccRCC^{IVC}) [1]–[3]. While constituting a high-risk setting in general, there still is substantial clinical heterogeneity within the ccRCC^{IVC} subgroup – with reported 5-year survival rates ranging from 37 % to 65 % for non-metastasized patients treated with nephrectomy and tumor thrombectomy [4]–[9]. Regarding this discrepancy, biomarkers are urgently needed to identify patients with a specifically high risk of cancer relapse [10], [11]. Potentially, this subgroup of ccRCC^{IVC} patients may also benefit from adjuvant systemic therapy and additional follow-up examinations.

MicroRNAs (miRs) as biomarker candidates are post-transcriptional regulators of gene expression in various cancer entities [12]–[14]. Regarding ccRCC, several studies demonstrated the prognostic impact of miR expression levels in tumor tissue [15]–[17]. Previously, Vergho et al. established a combined risk classifier for patients with ccRCC^{IVC} receiving nephrectomy and thrombectomy in curative intention [10]. Based on miR-21, miR-126 and miR-221 expression in tumor tissue, the risk classifier significantly stratified patients regarding cancer-specific survival in a

single-center cohort (*n* = 37) – with a 5-year cancer-specific survival (CSS) of 78 % vs. 18 % in the favorable and the unfavorable subgroup, respectively [10].

To further assess the miR-based risk classifier as a prognostic tool in ccRCC^{IVC} patients, we retrospectively evaluated it within an independent cohort (*n* = 56) from the Department of Urology, University of Regensburg (Regensburg, Germany). Cut-off values for miR expression levels as well as internal classifier weights were transferred from the previous pilot study [10], in order to test its transferability to independent study cohorts. Figure 1 illustrates the course of our study.

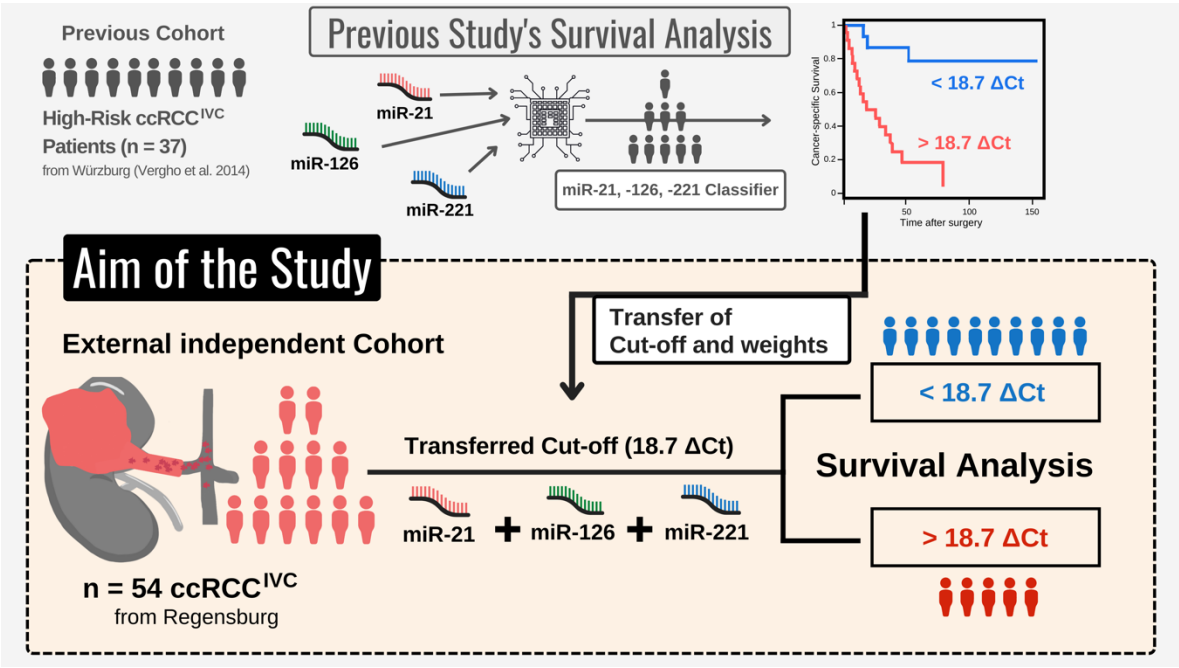

Fig. 1. Course of the study – using a microRNA (miR)-based risk classifier established previously [10], we examined the prognostic impact of miR-21, miR-126, and miR-221 expression in an independent cohort of clear cell renal cell carcinoma samples with infiltration of the inferior vena cava (ccRCC^{IVC}; *n* = 54). To assess the transferability of the miR-based risk classifier, cut-off value and weights were identical to the previous study.

2. Materials and Methods

2.1. Tumor Tissue Samples and Patients

Paraffin-embedded primary ccRCC^{IVC} tumor-samples of 56 subjects who underwent radical surgery were aggregated by the Department of Urology, University of Regensburg, Germany (1997–2006). A uropathologist selected sample-regions with > 90 % cancerous tissue. Follow-up data were collected by the Department of Urology, University of Regensburg (Regensburg, Germany). The study was approved by the local Ethics Committee (Regensburg: Nr. 08/108). Detailed characteristics of the study cohort are summarized in Table 1.

82 2.2. RNA Extraction and qRT-PCR

83 Using the RecoverAll™ Total Nucleic Acid Isolation Kit (Thermo Fisher Scientific, Waltham, MA),
84 total RNA from paraffin-embedded samples was isolated according to the manufacturer's
85 instructions. RNA concentration and 260/280 ratio were analyzed by Spark® 10M (TECAN,
86 Männedorf, Switzerland). cDNA was synthesized from total RNA with stem-loop reverse
87 transcription primers (TaqMan microRNA Assay protocol, Applied Biosystems, Birchwood, UK).
88 TaqMan microRNA Assay kit was used to quantify miR expression according to manufacturer's
89 protocols. Samples showing a standard deviation > 0.5 were excluded (all reactions performed in
90 triplicates). Small nuclear RNA (RNU6b) expression was used for normalization of miRs relative
91 expression values. Samples with expression levels of RNU6B > 30 Ct were not included in further
92 analyses. Relative miR expressions were calculated using the ΔCt-method (ΔCt sample = Ct miR of
93 interest − Ct RNU6b). To calculate fold changes in miR expression between samples, the $2^{\Delta\Delta Ct}$
94 method (in this study, referred to as the ΔΔCt method) was used.

95 2.3. Statistics and computational analysis

96 To evaluate the validity of the miR-based risk classifier – (4.592 × ΔCt miR-21) + (-3.892 × ΔCt
97 miR-126) + (-1.938 × ΔCt miR-221) – weights and cut-off values (> 18.7 ΔCt = "unfavorable
98 subgroup", < 18.7 ΔCt = "favorable subgroup") were transferred from the pilot study [10] and
99 applied in order to stratify the $ccRCC^{IVC}$ study cohort from Regensburg and perform Kaplan-Meier
100 analyses. Within the risk classifier formula, a negative factor indicates that higher expression levels
101 correlate with longer survival, while a positive factor correlates with shorter survival. For further
102 analysis, we transferred cut-off values for miR-21 (8.17 ΔCt), miR-126 (3.57 ΔCt) and miR-221
103 expression (1.84 ΔCt) to evaluate their predictive potential in the new cohort using the Kaplan-Meier
104 survival analysis. Kaplan-Meier, log-rank tests, univariate and multivariate Cox regression analysis
105 as well as partial effects on outcome analysis were performed using Python LifeLines Package
106 Version 0.27.0 [18]. Depending on the distribution of the data, Student's t-test or Mann-Whitney-
107 U-Test was used to analyze differences between miR expressions.

108

109 **3. Results**

110 Table 1 summarizes the basic clinical and pathological characteristics of our study cohort.
111 Detailed follow-up information were available for 54 of 56 $ccRCC^{IVC}$ patients (96.4 %).

112

113 **Table 1.** Clinical and pathological patient characteristics (*n* = 56). Detailed follow-up information were available
114 for 54 patients.
115

Characteristics	
Median Follow-up	94 (1 – 190) months
Median Age	67 (41 – 89) years
Sex	
female	22 (39.3 %)
male	34 (60.7 %)

no	29 (51.8 %)
Cancer-related death	
yes	13 (23.2 %)
no	43 (76.8 %)

116

117 3.1. Association of miR-21, -126 and -221 Expression with Clinicopathological Characteristics

118 To investigate the impact of miR-21, -126 and -221 within our ccRCC^{IVC} cohort, we associated
119 expression levels of miR-21, miR-126 and miR-221 to relevant clinical parameters. Figure 2 illustrates
120 the results.

121 At time of surgery, 11 of 56 ccRCC^{IVC} patients (19.6 %) were diagnosed with nodal metastasis.
122 In cases with positive nodal status, a trend towards up-regulation of miR-21 (p = 0.065) and a
123 significant down-regulation of miR-126 (p < 0.001) were observed. For miR-221, no statistical
124 association to nodal status could be shown.

125 During the follow-up period, distant metastasis emerged in 21 of 56 ccRCC^{IVC} patients (37.5 %).
126 As shown in Figure 2b, we observed a significant up-regulation of miR-21 (p < 0.001) and down-
127 regulation of miR-126 (p < 0.0001) as well as a trend towards downregulation for miR-221 (p = 0.06)
128 in ccRCC^{IVC} samples of patients with metastasized disease.

129 13 of 56 patients with ccRCC^{IVC} (23.2 %) died during the follow-up period due to cancer (cancer-
130 related death, CRD). Regarding miR expression levels, we found a significant up-regulation of miR-

21 (p < 0.0001) and a down-regulation of miR-126 (p < 0.001) in CRD cases. Instead, miR-221 expression did not show a statistically significant association to CRD in this analysis (p = 0.27).

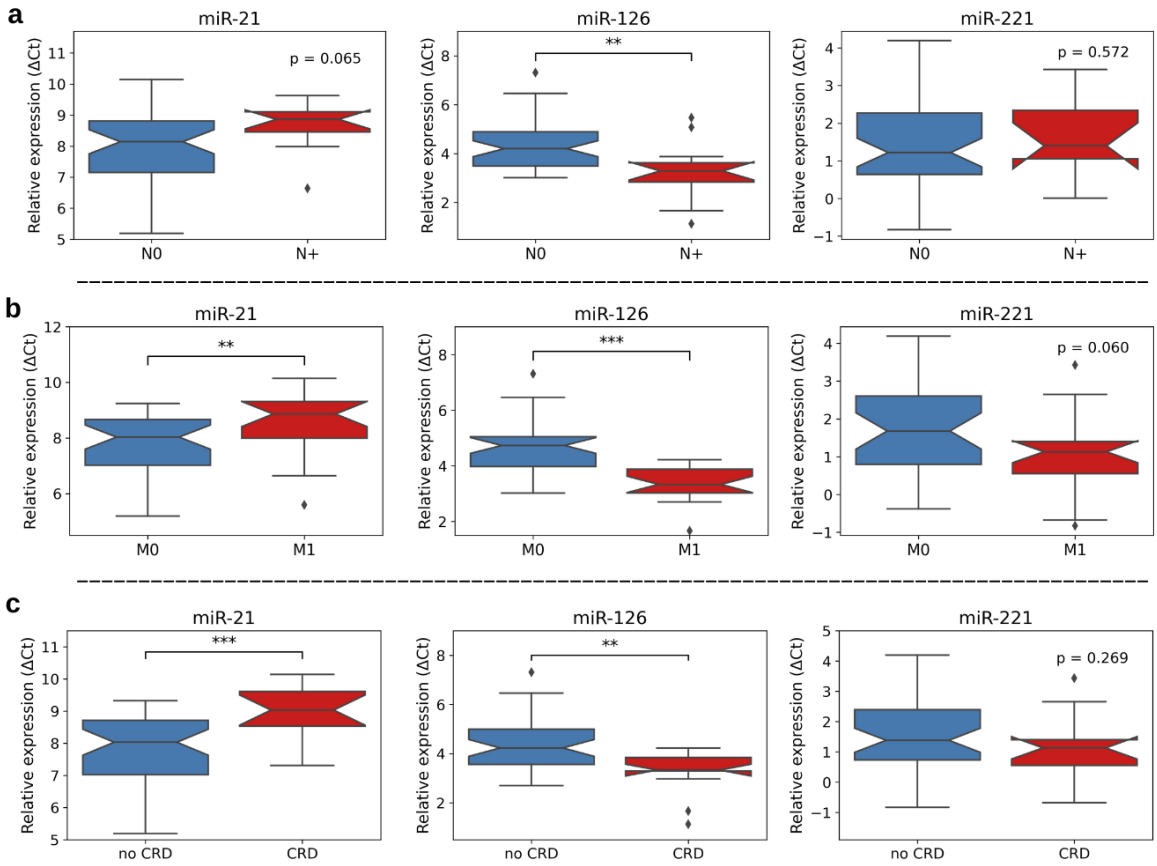

Fig. 2. miR-21, -126 and -221 expression levels depending on lymphonodal status (a), distant metastases (b) and cancer-related death (c). Significant changes between subgroups were calculated using unpaired Student's t test or Mann-Whitney-U test. p < 0.05 *; p < 0.001**; p < 0.0001***.

3.2. Cox regression Analysis

Next, we performed a univariate Cox regression analysis to further assess the prognostic potential of miR-21, -126, and -221 expression levels as predictors of CRD. Detailed follow-up information were available for 54 of 56 cases with a median of 94 months.

As summarized in Table 2, miR-21 and miR-126 significantly predicted the occurrence of CRD in our study cohort (p = 0.007 for miR-21, p = 0.00035 for miR-126). In contrast, miR-221 expression in tumor tissue did not display significant prognostic potential (p = 0.28). Regarding further clinical parameters, significant results were also observed for nodal involvement, metastatic status and Fuhrman grade.

148 **Table 2.** Univariate and multivariate Cox regression of ccRCC^{IVC} patients for miR expression levels and
149 clinicopathological parameters. 95 % Confidence intervals (CI) shown for Hazard ratios. *p* values were computed
150 using the chi-squared test. $p < 0.05$ *; $p < 0.001$ **; $p < 0.0001$ ***
151

	Cancer-related death			
	Univariate analysis		Multivariate analysis	
Parameters	Hazard Ratio (95 % CI)	*P* value	Hazard Ratio (95 % CI)	*P* value
miR-21	3.79 (1.55 – 9.26)	**0.003***	3.51 (1.2 – 10.2)	**0.02***
miR-126	0.19 (0.09 – 0.42)	**0.00035*****	0.18 (0.075 – 0.43)	**0.0001****
miR-221	0.74 (0.46 – 1.19)	0.21	0.65 (0.38 – 1.13)	0.13
Age	0.98 (0.92 – 1.03)	0.42		
Sex	2.10 (0.58 – 7.65)	0.26		
Tumor size	1.01 (1.00 – 1.03)	0.07		
Fuhrman Grade	3.79 (1.27 – 11.33)	**0.02***		
Nodal status	6.70 (2.09 – 21.47)	**0.001***		
Distant metastasis	∞	NA		

Abbreviation: CI, confidence interval; ∞ / NA: In case of distant metastasis as clinical predictor of CRD, the coefficient was not estimable (positively infinite). Hazard ratio and p-value were therefore not shown.

152

153 Additionally, multivariate Cox regression for the three miR candidates yielded statistical
154 significance for miR-21 ($p = 0.02$, Hazard Ratio 3.51) and miR-126 expression ($p = 0.0001$, Hazard
155 Ratio 0.18) as predictors of CRD within our ccRCC^{IVC} cohort. Despite a Hazard Ratio of 0.65, miR-221
156 expression again did not meet statistical significance as predictor of CRD ($p = 0.13$).

157 To further estimate the prognostic impact of single miR candidates from multivariate Cox
158 regression, we analyzed their partial effect on CSS for varying miR expression levels (Fig. 3). For miR-
159 21, higher relative expression levels were associated with lower CSS (Fig. 3a). In contrast, higher
160 expression levels of miR-126 as well as miR-221 were associated with higher CSS (Fig. 3b, c).

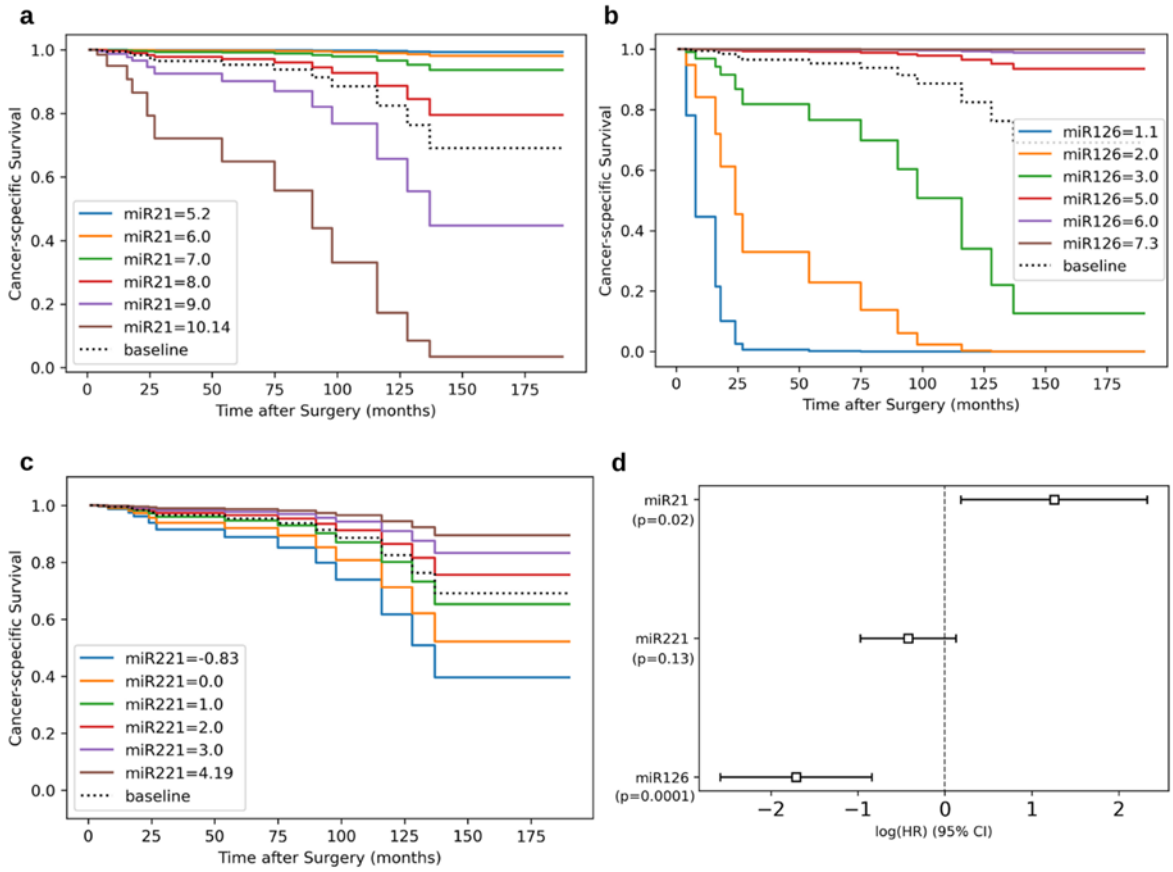

Fig. 3. (a–c) Partial effects of miR-21 (a), miR-126 (b) and miR-221 (c) expression levels on cancer-specific survival. The baseline represents median relative expression for each miRNA (miR-21 = 8.34 ΔCt, miR-126 = 4.0 ΔCt, miR-221 = 1.3 ΔCt). Blue line represents minimum and brown line the maximum relative expression of each miRNA in present study cohort. (d) Forest plot representing log Hazard Ratios (HR) from multivariate Cox regression of miR-21, -126, -221 for cancer-related death (CRD). p values were computed using the chi-squared test.

3.3. Kaplan Meier Analyses for single miR expression and the Risk Classifier

To investigate the prognostic transferability of single miRNAs, survival analyses using the cut-offs from Vergho et al. [10] were performed. Both, miR-21 and miR-126 showed a strong predictive significance in the Kaplan-Meier survival analysis (Fig. 4a, b). However, differences regarding CSS of miR-221 high vs. low expressing tumor specimens (Fig. 4c) did not reach statistical significance (p = 0.25).

To validate the predictive potential of the risk classifier (Fig. 4d), the cut-off level of 18.7 ΔCt (> 18.7 ΔCt = unfavorable subgroup, < 18.7 ΔCt = favorable subgroup) was used to stratify the validation cohort consisting of n = 54 ccRCC^{IVC} tissue samples. Out of 13 CRD cases in total, the classifier correctly identified 12 patients who suffered from CRD as members of the unfavorable subgroup (92.3 %; > 18.7 ΔCt). Overall, a sensitivity of 92.3 % (CI 95 %: 62.1 % – 99.6 %) and a specificity of 61.0 % (CI 95 %: 44.5 % – 75.4 %) were reached. Difference in 5-years and 10-years CSS

was 100 % vs 70 % and 94 % vs 31 % between the favorable and the unfavorable subgroup, respectively.

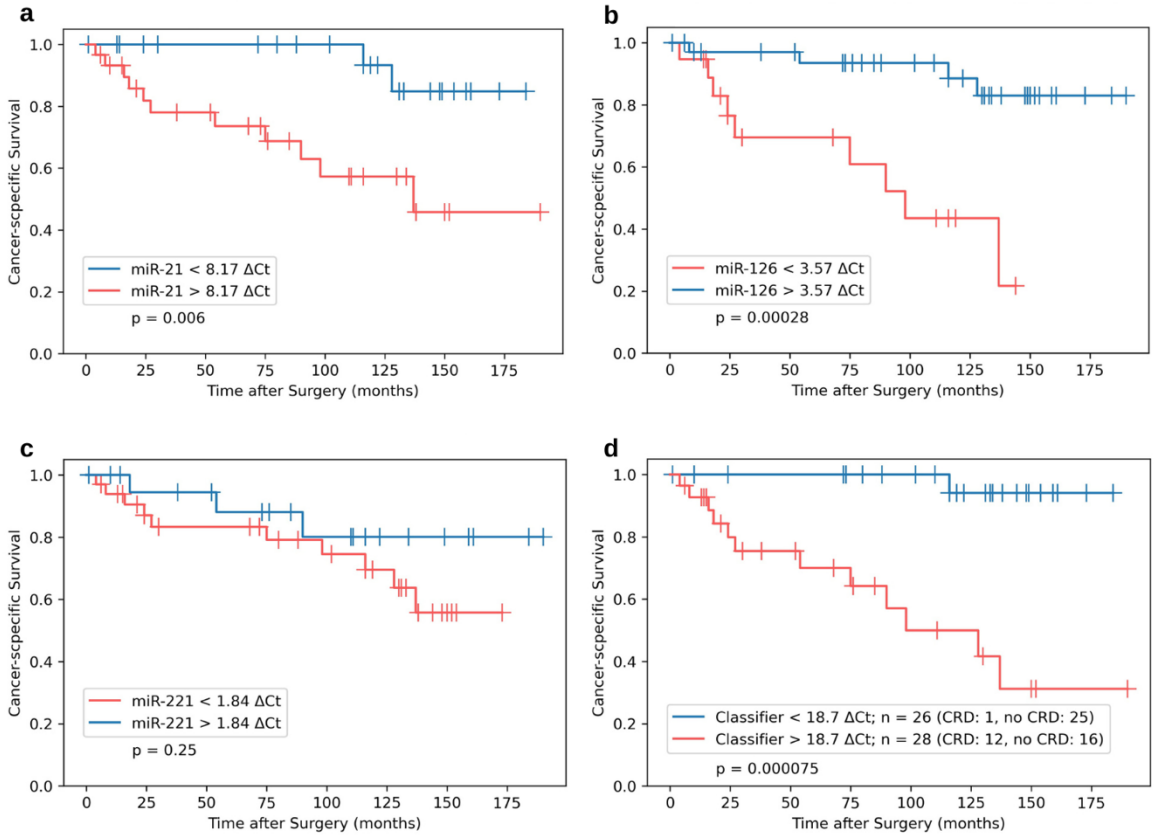

Fig. 4. Kaplan Meier survival analysis for CSS for external independent ccRCC^{IVC} (*n* = 54) cohort from Regensburg stratified by miR-21 (a), miR-126 (b) and miR-221 (c) expression levels. (d) Combined miR-based risk classifier (miR-21, -126, -221) using identical cut-offs and weights from a previous publication [10]. *p* values from log-rank tests are shown within each plot.

4. Discussion

ccRCCs infiltrating the inferior vena cava represent a clinically relevant high-risk subgroup. Still, there is substantial clinical heterogeneity within this distinct subgroup – and biomarkers are needed to assess the individual risk of progression. In general, adjuvant therapy with tyrosine kinase inhibitors (TKI) or immune checkpoint blockers could be a promising therapeutic option after nephrectomy – especially for patients suffering from high-risk RCC. However, European kidney cancer guidelines currently do not contain strong recommendations towards adjuvant therapies due to the mixed outcome in clinical trials [19]. For the TKI sunitinib, one trial displayed improved disease-free survival (DFS) for patients – while showing no significant differences in overall survival (OS) [20]. Additionally, another phase 3 trial did not detect significant survival effects for adjuvant sunitinib or sorafenib in nonmetastatic high-risk renal cell carcinoma [21]. Due to the sobering TKI

199 results, research efforts were mainly shifted towards immune checkpoint blockers. For the PD-1
200 (Programmed Cell Death Protein 1) inhibitor pembrolizumab, KEYNOTE-564 trial detected improved
201 progression-free survival (PFS) in an adjuvant setting after nephrectomy [22].

202 4.1. Evaluating a miR-based Risk Classifier for RCC with Infiltration of the Vena Cava

203 To estimate the individual risk of patients suffering from ccRCC^{IVC}, members of our research
204 group have established a risk classifier based on the tissue expression of miR-21, miR-126, and miR-
205 221 [10]. Former cohort contained tumor tissue of *n* = 37 patients undergoing surgery at the
206 University Hospital of Würzburg, Germany. In this study, we externally validated the prognostic
207 potential of the miR-based risk classifier. Therefore, we examined an independent cohort of ccRCC^{IVC}
208 from the University of Regensburg, Germany (*n* = 56). To test the transferability and usability of the
209 classifier within an external tissue cohort, we applied identical cut-off values and weights as in the
210 previous pilot study.

211 Regarding clinicopathological characteristics of our study cohort, low miR-126 expression was
212 significantly associated with a positive lymphonodal status at time of surgery. Moreover, occurrence
213 of metastases during follow-up was significantly associated with higher miR-21 and lower miR-126
214 levels. Tumor tissue from patients suffering from CRD was also characterized by a significant
215 upregulation of miR-21 and a downregulation of miR-126. Within univariate cox regression, miR-21
216 and miR-126 showed prognostic significance regarding cancer-specific survival (CSS). Lower levels
217 of miR-221 in tumor tissue and its association with CRD did not reach statistical significance. Beyond
218 miR expression, Fuhrman grade, lymphonodal status and occurrence of metastasis emerged as
219 prognostically relevant. Next, we added a multivariate Cox regression for the three miR candidates.
220 Again, this study identified miR-21 and miR-126 expression to significantly impact CRD. Kaplan Meier
221 analyses based on cut-off values determined previously by Vergho et al. [10] confirmed the
222 significant influence of miR-21 as well as miR-126 expression levels on CSS. Finally, applying the miR-
223 based classifier using identical cut-off values and weights split patients in two groups. Of note, the
224 classifier nearly stratified the study cohort in two halves – with *n* = 26 patients belonging to the
225 favorable and *n* = 28 patients belonging to the unfavorable subgroup. Regarding the substantial
226 difference in CSS between both groups, adjuvant therapies appear promising especially for the
227 unfavorable subgroup of ccRCC^{IVC} patients.

228 4.2. Functional Roles of miR-21, miR-126, and miR-221 in Cancer

229 After confirming the prognostic potential of the miR classifier using the validation cohort from
230 Regensburg, we were interested in previously reported functions of these miRs in RCC and other
231 malignancies. For miR-21, several researchers demonstrated oncogenic effects in various cancers,
232 including RCC [23], [24]. Among the prominent miR-21 target genes are key players of apoptosis

233 induction like PDCD4 (Programmed Cell Death 4) [25] and genes like PTEN (Phosphatase and Tensin
234 Homolog) [23]. Latter is an established tumor suppressor gene best known for regulating PI3K/Akt
235 signaling. In contrast to miR-21, miR-126 acts as a tumor suppressor in tumor tissue, e. g. by
236 targeting ROCK1 (Rho Associated Coiled-Coil Containing Protein Kinase 1) [26] and VEGFA (Vascular
237 Endothelial Growth Factor A) [27]. For miR-221, oncogenic versus protective functions appear to
238 depend on the underlying cancer entity, as researchers demonstrated both roles [28]–[30]. For RCC,
239 a downregulation of miR-221 appears well in line with previous publications. Specifically, miR-221
240 is reported to regulate KDR (Kinase Insert Domain Receptor) – also known as VEGFR2 (Vascular
241 Endothelial Growth Factor Receptor 2) – in ccRCC [31] and prostate cancer [32], thereby regulating
242 the sensitivity towards sunitinib. In summary, among diverse tumorigenic functions of these miRs,
243 all three candidates prominently influence angiogenesis-related pathways (so-called
244 AngiomiRs) [33], [34]. Given that not all ccRCCs depend on angiogenic signaling to the same degree
245 [35], it is tempting to assume that the unfavorable subgroup identified by our risk classifier could
246 benefit from adjuvant anti-angiogenic therapy.

247 4.3. Limitations and Future Directions

248 Our study has several limitations. Leaving aside the special RCC subgroup investigated here,
249 sample size of our study is relatively small. Moreover, we purposely did not adjust cut-off values and
250 individual miR weights determined previously in order to check the transferability of the risk
251 classifier to external tissue cohorts. More research is needed – ideally in a prospective setting – to
252 further validate the risk classifier in a clinical setup and to elucidate whether sub-classification of
253 $ccRCC^{IVC}$ is able to identify patients most susceptible towards adjuvant therapy.

254 **5. Conclusions**

255 While RCC extending into the inferior vena cava represents a high-risk setting, there is still
256 substantial clinical heterogeneity within this patient subgroup. Previously, Vergho et al. established
257 a miR-based risk classifier - containing miR-21, miR-126 and miR-221 expression – which significantly
258 predicted CSS for patients from this subgroup. To validate this classifier, we examined its impact on
259 an external and independent patient cohort. Using identical cut-off values for single miRs and
260 identical weights within the classifier, we confirmed a highly significant risk stratification within the
261 new cohort. Patients with an unfavorable constellation according to the miR-based classifier could
262 especially benefit from adjuvant therapy and continuous follow-up examinations.
