ABSTRACT

The sequencing of human virus genomes from wastewater samples is an efficient method for tracking viral transmission and evolution at the community level. However, this requires the recovery of viral nucleic acids of high quality. We developed a reusable tangential-flow filtration system to concentrate and purify viruses from wastewater for whole-genome sequencing. A pilot study was conducted with 94 wastewater samples from four local sewersheds, from which viral nucleic acids were extracted, and the whole genome of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) was sequenced using the ARTIC V4.0 primers. Our method yielded a high probability (0.9) of recovering complete or near-complete SARS-CoV-2 genomes (>90% coverage at 10× depth) from wastewater when the COVID-19 incidence rate exceeded 33 cases per 100 000 people. The relative abundances of sequenced SARS-CoV-2 variants followed the trends observed from patient-derived samples. We also identified SARS-CoV-2 lineages in wastewater that were underrepresented or not present in the clinical whole-genome sequencing data. The developed tangential-flow filtration system can be easily adopted for the sequencing of other viruses in wastewater, particularly those at low concentrations.

KEYWORDS

SARS-CoV-2, COVID-19, whole-genome sequencing, tangential-flow filtration, wastewater-based epidemiology

SYNOPSIS

The tangential-flow filtration method extracts viral nucleic acids of high enough quality from wastewater for robust and successful whole-genome sequencing.

50

51

52 **INTRODUCTION**

53 The global spread of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) has
54 facilitated the emergence of genome mutations, resulting in new lineages that further threaten
55 public health.[1] Whole-genome sequencing (WGS) of clinical samples is a powerful method for
56 tracking the spread of various SARS-CoV-2 lineages,[2] but this can be expensive, slow, and subject
57 to biased sampling. Furthermore, the frequency of clinical testing has declined, aided by the
58 availability of rapid at-home testing kits. WGS of SARS-CoV-2 in wastewater samples
59 circumvents the issues as a high-throughput and more comprehensive strategy that monitors a
60 larger portion of the population.[3-6] Successful WGS of SARS-CoV-2 in wastewater samples relies
61 on the depth (the number of times a nucleotide is sequenced)[7] and breadth of genome coverage
62 (hereafter, coverage; the percentage of nucleotide positions sequenced to a given depth).[7] Because
63 SARS-CoV-2 lineages differ by only a few mutations, greater depth and coverage are needed to
64 quantify lineage abundance and detect low-frequency mutations.[8, 9]

65 Different virus concentration methods have been developed for polymerase chain reaction
66 (PCR)-based detection of viral genes from wastewater.[10-13] However, the nucleic acids recovered
67 with these methods may not be suitable for WGS—PCR assays typically target <1% of the
68 genome. Sequencing inhibitors, such as humic acids, and background nucleic acids from
69 prokaryotes and eukaryotes are likely to reduce the genome coverage of SARS-CoV-2. Indeed,
70 near-complete (>90%) SARS-CoV-2 genomes are not recovered from most samples (>85%) when
71 aluminum hydroxide is used to directly precipitate viruses without separating viruses from other
72 microorganisms in wastewater.[14] The removal of wastewater solids before the Amicon/Centricon
73 ultra-centrifugal concentration[15] or electronegative membrane filtration[16] can improve sequencing

74 success, but the quality of the extracted genomes can vary and random sequencing failures can
75 occur.[17]

76 We report a reusable and nonselective tangential-flow filtration system to concentrate and
77 purify viruses from wastewater for WGS. We evaluated the robustness of the method to recover
78 complete or near-complete SARS-CoV-2 genomes using the samples collected from four local
79 sewersheds over six months. We subsequently compared the findings with those from patient-
80 derived clinical samples at the County level. Finally, the timing of lineage detection was compared
81 among clinical WGS, wastewater WGS, and quantitative reverse transcription polymerase chain
82 reactions (RT-qPCR).

83

84 **MATERIALS AND METHODS**

85 **Wastewater sample collection**

86 Time- or flow-weighted 24-hr composite influent samples were collected every 1 or 2
87 weeks between October 1 and December 16, 2021, and between January 18 and April 12, 2022,
88 from three wastewater treatment plants covering four sewersheds that serve ~80% of the total
89 population of Erie County (New York): Tonawanda, Kenmore-Tonawanda, Amherst, and Bird
90 Island (**Table S1**; **Figure S1**). Influent was collected by an autosampler every 30 min, and the
91 samples were kept at 4 °C in high-density polyethylene bottles that were cleaned with 10% bleach.
92 The samples were transported on ice packs and stored at 4 °C until they were processed.

93

94 **Virus concentration from wastewater**

95 Wastewater samples (125 mL) were centrifuged in sterile bottles at 10 000 × *g* for 15 min
96 at 4 °C to remove large wastewater solids, prokaryotic and eukaryotic cells, and other debris. The

97 supernatant was concentrated in a Vivaflow laboratory cross flow cassette system (Sartorius)
98 equipped with a 30-kDa Hydrosart ultrafilter membrane (Sartorius) at a feedline flow rate of 8.5
99 mL/min (**Figure S2**). The residual liquid in the ultrafilter membrane and connected tubing was
100 blown with air into the sample reservoir. The concentrate (~25 mL) in the reservoir was then
101 collected, overlayed with 5 mL of a 20% (v/v) sucrose solution and ultracentrifuged at 100 000 ×
102 *g* for 45 min at 4 °C in an SW 32 Ti rotor using an Optima XE series centrifuge (Beckman Coulter).
103 Immediately after the ultracentrifugation, the pellet was resuspended in 200 µL phosphate-
104 buffered saline (pH 7.4; Gibco) and stored at −80 °C ~two weeks until nucleic acid extraction.
105 After use, the ultrafilter membranes were immediately flushed with ~100 mL of 0.5 M
106 NaOH solution preheated to 55 °C at a feedline flow rate of 8.5 mL/min. The NaOH solution was
107 then recirculated for 20–30 min at the same flow rate. The cleaned membrane was stored in 0.5 M
108 NaOH at 4 °C. Cleaning efficiency was verified on six random days by processing 125 mL of
109 autoclaved Milli-Q water with the same concentration procedure. The absence of SARS-CoV-2
110 genes through washed filters were confirmed by RT-qPCR (**Figure S3**).
111
112 **Nucleic acid extraction and RT-qPCR**
113 Viral nucleic acids were extracted from the concentrated samples with QIAamp viral RNA
114 mini kits (Qiagen) and eluted in 60 µL AVE buffer (Qiagen) per the manufacturer's instructions.
115 One-step RT-qPCR was performed to quantify the SARS-CoV-2 N gene according to the CDC
116 N2 assay[18] and to determine the presence/absence of specific S gene mutations, including WT493-
117 498, Q493R and Q498R, delH69/V70, and delL24/P25/P26 and A27S as variant determinants for
118 Delta, generic Omicron, Omicron BA.1, and Omicron BA.2, respectively, following methods
119 published previously (**Table S2**).[19, 20] The limit of detection for the SARS-CoV-2 N gene was

120 determined to be 1.8 gene copies/μL, and the limit of quantification was determined to be 5 gene
121 copies/μL following a method as described previously (**Figure S4**).[21] A checklist of the MIQE
122 (minimum information for publication of quantitative real-time PCR experiments) guidelines[22] is
123 provided in **Table S3**. All RT-qPCR assays were conducted in duplicates on a CFX96 Touch real-
124 time PCR detection system (Bio-Rad), and the threshold cycle (C_T) value was determined using a
125 CFX Maestro Software (Version 4.0, Bio-Rad). To remove PCR inhibition, the extracted nucleic
126 acids were diluted 5- or 10-fold in nuclease-free water before RT-qPCR analyses (**Figure S5**).
127 Detailed procedures of RT-qPCR inhibition test, reaction compositions, thermocycling conditions,
128 and determination of the limits of detection and quantification are described in the Supporting
129 Information.
130

131 **SARS-CoV-2 whole-genome sequencing (WGS)**

132 The quality of the extracted nucleic acids was assessed with the Agilent Fragment
133 Analyzer. WGS of SARS-CoV-2 was performed following a modified ARTIC protocol[23] using
134 the V4.0 nCOV-2019 amplicon panel (IDT). Briefly, 8 μL of nucleic acid extracts was reverse
135 transcribed to cDNA with random hexamers using the Invitrogen SuperScript IV first-strand
136 synthesis system (Thermo Fisher Scientific) according to the manufacturer's protocol. The cDNA
137 was amplified with two primer pools using Q5 hot-start high-fidelity 2× master mix (New England
138 BioLabs) with the following parameters: 98 °C for 30 s, 25 cycles of 98 °C for 15 s and 65 °C for
139 5 min. The resulting amplicons from both primer pools were combined. Excess primers and
140 reagents were removed with 1× AMPure XP beads (Beckman Coulter), and the amplicons were
141 eluted in EB buffer (Qiagen). The total eluted volume of amplicons was input to generate libraries
142 using the NEBNext Ultra II DNA library prep kit (New England BioLabs) without fragmentation

143 per the manufacturer's protocol. Individual samples were then barcoded and pooled for
144 quantification using the sparQ Universal Library Quant kit (QuantaBio) for Illumina sequencing.
145 The libraries were diluted to 10 pM and sequenced on an Illumina MiSeq instrument (V3
146 chemistry, PE300) with 1% PhiX as internal control.
147

148 **Bioinformatic analysis**

149 The Illumina sequencing output files were demultiplexed using bcl2fastq (v2.20.0.422) to
150 convert into FASTQ files. Initial quality control was performed through FastQ Screen.[24] Samples
151 were then processed using the UB Genomics and Bioinformatics Core SARS-CoV-2 analysis
152 pipeline (https://github.com/UBGBC/fastq-to-consensus). Briefly, adapters were trimmed before
153 sequencing reads were aligned to the SARS-CoV-2 reference genome (MN908947.2) using the
154 BWA-MEM algorithm.[25] Variants, insertions, and deletions were then called using BCFtools
155 (v.1.10.2),[26] requiring a minimum depth per nucleotide position of 10× or 50× and generating VCF
156 file outputs along with a final consensus FASTA file for each input sample. The resulting VCF
157 and depth mpileup files were used as input into Freyja to perform lineage composition analysis
158 (https://github.com/andersen-lab/Freyja).[5] The coverage (--covcut) was specified at 10× or 50×,
159 and only confirmed lineages were reported. The Freyja pipeline was selected because of its high
160 accuracy and efficiency.[5]
161

162 **Patient-derived SARS-CoV-2 data**

163 The daily cases of COVID-19 during the sampling periods in the studied sewersheds were
164 extracted from the Erie County Wastewater Monitoring Dashboard.[27] The COVID-19 incidence
165 rates (per 100 000 population in the sewershed) were then calculated as 7-day rolling averages.

166 The patient-derived WGS data at the County level were downloaded from the Global Initiative on
167 Sharing All Influenza Data (GISAID) database[28] with the location as "North America/USA/New
168 York/Erie County," collection date from "2021-10-01" to "2022-04-30", and low coverage
169 excluded (GISAID Identifier: EPI_SET_220906wr). Most of these samples were sequenced at
170 University at Buffalo.[29] On each collection date, the relative abundances of SARS-CoV-2 lineages
171 in the patient samples were calculated, and the number of patient samples that were collected for
172 sequencing were smoothed as 7-day rolling averages.
173

174 **Statistical analysis**

175 The probability of recovering >90% coverage of the SARS-CoV-2 genome at 10× depth at
176 a given RT-qPCR C_T value or COVID-19 incidence rate was predicted by binary logistic
177 regression analysis. Data were visualized with Prism 9.2.0 (GraphPad Software) and the ggplot2[30]
178 package in R version 4.2.1.[31]
179

180 **Data availability**

181 Raw sequencing data are available in NCBI Sequence Read Archive (SRA) under the
182 BioProject ID: PRJNA877272. Codes for analyzing SARS-CoV-2 lineage in wastewater are
183 available at https://github.com/UBGBC/fastq-to-consensus.
184

185 **RESULTS AND DISCUSSION**

186 **Coverage and depth of SARS-CoV-2 genomes from wastewater**

187 Complete or near-complete SARS-CoV-2 genomes (>90% coverage) at 10× depth were
188 recovered from 68% (64/94) of the wastewater samples (**Table S4**). This success rate is 53% higher

189 than that in a SARS-CoV-2 wastewater sequencing study that applied aluminum hydroxide
190 flocculation and the ARTIC protocol.[14] A binary logistic regression analysis predicted a 0.9
191 probability of sequencing success (>90% coverage at 10× depth) when the C_T value of the SARS-
192 CoV-2 N gene was 31.8 (corresponding to ~3500 gene copies loaded for sequencing) (**Figure 1A**).
193 For comparison, at the 0.9 probability of sequencing success, C_T values of SARS-CoV-2 gene
194 ranged from <26 to ~29 with other workflows in previous pilot studies (**Figure S6**).[14-17] Our
195 workflow demonstrates higher coverage of SARS-CoV-2 genome at higher C_T values (lower gene
196 levels).

197 Most genomic regions were sequenced at a minimum depth of 50× (**Figure S7**). We noted
198 that three regions were often sequenced at lower depth (<10×): nucleotides 21750 to 22250 in the
199 S gene (amplicons 72 and 73) and 26750 to 27000 in the M gene (amplicon 89) (**Figure S7**).
200 Similar amplicon dropout issues were previously reported for a few amplicons using the ARTIC
201 V3 panel.[32, 33] We used ARTIC V4.0 primers, which address the V3 coverage issues but do not
202 include all the mutations in SARS-CoV-2 Delta and Omicron lineages in the primer design.[34] Other
203 wastewater factors may also explain the low-depth coverage within certain regions of SARS-CoV-
204 2 genome. First, the low concentrations of the SARS-CoV-2 genome in wastewater ($<10^5$ gene
205 copies/mL)[35] may have contributed to the lower sequencing depth. The presence of primer dimers
206 compete for primer-template interactions, resulting in reduced amplification efficiency.[36] Also,
207 mutations of SARS-CoV-2 genomes identified in wastewater but not in patient samples could
208 influence primer binding at some sites.[3, 6, 37] Our results suggest that up-to-date primer design and
209 optimization is critical to sequence emerging variants from wastewater.

210

211 **Robustness of SARS-CoV-2 WGS from wastewater**

212 *Influence of sewersheds*. The rates of sequencing success were similar for samples
213 collected from the four studied sewersheds: 70.8% (17/24) for Tonawanda, 72.0% (18/25) for
214 Kenmore-Tonawanda, 72.7% (16/22) for Amherst, and 65.2% (15/23) for Bird Island (**Table S4**).
215 Although the Bird Island sewershed serves a population that is larger than the other three (**Table**
216 **S1**), similar average C_T values were obtained for the SARS-CoV-2 N gene (33.5 for Tonawanda,
217 33.4 for Kenmore-Tonawanda, 34.2 for Amherst, and 34.1 for Bird Island) (**Table S4**), indicating
218 that similar genome levels were available for sequencing. Notably, the Bird Island wastewater
219 treatment plant collects wastewater exclusively through combined sewer systems (**Table S1**). A
220 large fraction of sequencing inhibitors, such as humic acids and heavy metals, in the stormwater
221 runoff may slightly reduce the WGS success rate.[38, 39]

222 *Influence of COVID-19 incidence.* The probability of sequencing success was >0.9 when
223 the COVID-19 incidence rate was >33/100 000 persons but decreased to 0.75 when the incidence
224 rate was 25.2/100 000 persons (**Figure 1B**). A previous study reported a probability of 0.75 to
225 quantify SARS-CoV-2 gene in wastewater by RT-qPCR when the 14-day COVID-19 case rate
226 was 152/100 000 persons.[40] In that study, viruses were concentrated from solids-removed influent
227 samples by 10-kDa Centricon ultra-filters.[40] We are not aware of other wastewater sequencing
228 studies that have calculated SARS-CoV-2 WGS success rates with regard to the incidence rate,
229 but our results suggest that SARS-CoV-2 WGS with the viruses recovered by tangential-flow
230 filtration method can be successfully applied at low COVID-19 incidence rates.

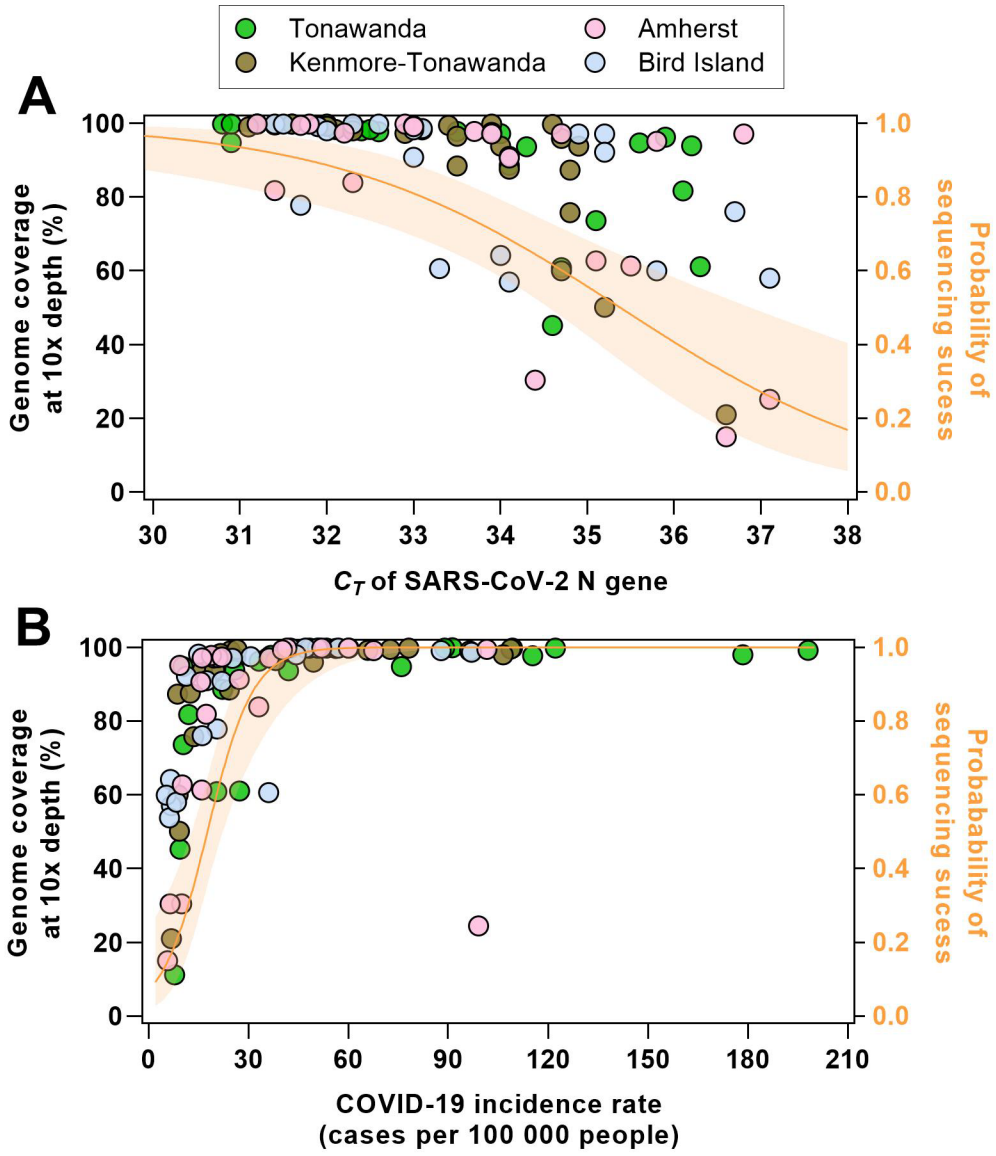

Figure 1. Coverage of the SARS-CoV-2 genome at 10× depth and the probability of sequencing success (>90% coverage at 10× depth) with regard to C_T value of the SARS-CoV-2 N gene measured with RT-qPCR (A) and the COVID-19 incidence rate (rolling 7-day average of cases per 100 000 people) (B). The probability of sequencing success was calculated according to a binary logistic regression analysis.

237

238 **Lineage distributions estimated by wastewater and clinical data**

239 Most of our wastewater samples were sequenced to an average depth of >50× per 250-
240 nucleotide-region across the genome (**Figure S7**). Although the estimated lineage abundances at
241 sequencing depths of 10× and 50× were very similar (**Figure S8**), we only reported lineage
242 distributions estimated by the WGS data filtered at a depth of 50×.

243 Nine dominant groups of lineages were identified in the wastewater samples: AY.* (Delta),
244 B.1.617.2 (Delta), B.1.2, B.1.1.529 (Omicron), BA.1/BA.1.1 (Omicron), BA.1.1.16 (Omicron),
245 other BA.1.* (Omicron), BA.2.12/BA.2.12.1 (Omicron), and other BA.2.* (Omicron). The
246 prevalence of Delta AY.* lineages in wastewater in October–December 2021 was coincident with
247 the lineages observed via clinical surveillance (**Figure 2**). Two Omicron infection waves in 2022
248 (BA.1 in January/February and BA.2 in March/April) predicted from the wastewater data aligned
249 with clinical data (**Figure 2**). Remarkably, wastewater sequencing revealed lineages that were
250 underrepresented or not present in the clinical data. Specifically, the B.1.2 lineage was abundant
251 in the Kenmore-Tonawanda sewershed in October but was not detected in patient samples from
252 that time (**Figure 2A**). Moreover, in January/February of 2022, the BA.1/BA.1.1 lineages were
253 prevalent in patient samples (**Figure 2A**), whereas the BA.1.1.16 lineage dominated in the
254 wastewater samples (**Figure 2B–E**). Notably, the genome sequences of the BA.1/BA.1.1 and
255 BA.1.1.16 lineages are similar, which might affect the predictions of their relative abundance.

256 The reason that B.1.2 lineage identified in wastewater samples but largely absent from
257 patient samples is unclear. The Freyja pipeline identified B.1.2 on the basis of a mutation
258 spectrum, consisting of 13 nucleotide substitutions (A18424G, A23403G, C10319T, C1059T,
259 C14408T, C21304T, C241T, C27964T, C28472T, C28869T, C3037T, G25563T, and G25907T),

260 three of which (C1059T, C21304T, and G25563T) overlap the mutations in highly abundant
261 Delta lineages circulating at the time. Furthermore, the B.1.2 mutation spectrum does not share a
262 strong correlation with any of the mutation spectra of Delta lineages (**Figure S9**). This is less
263 likely a misassignment by the pipeline. Taken together, our findings suggest that the WGS of
264 patient samples can miss SARS-CoV-2 lineages circulating in the community. Those lineages
265 may not be clinically relevant, but future research is needed to understand their roles in viral
266 evolution and lineage emergence.

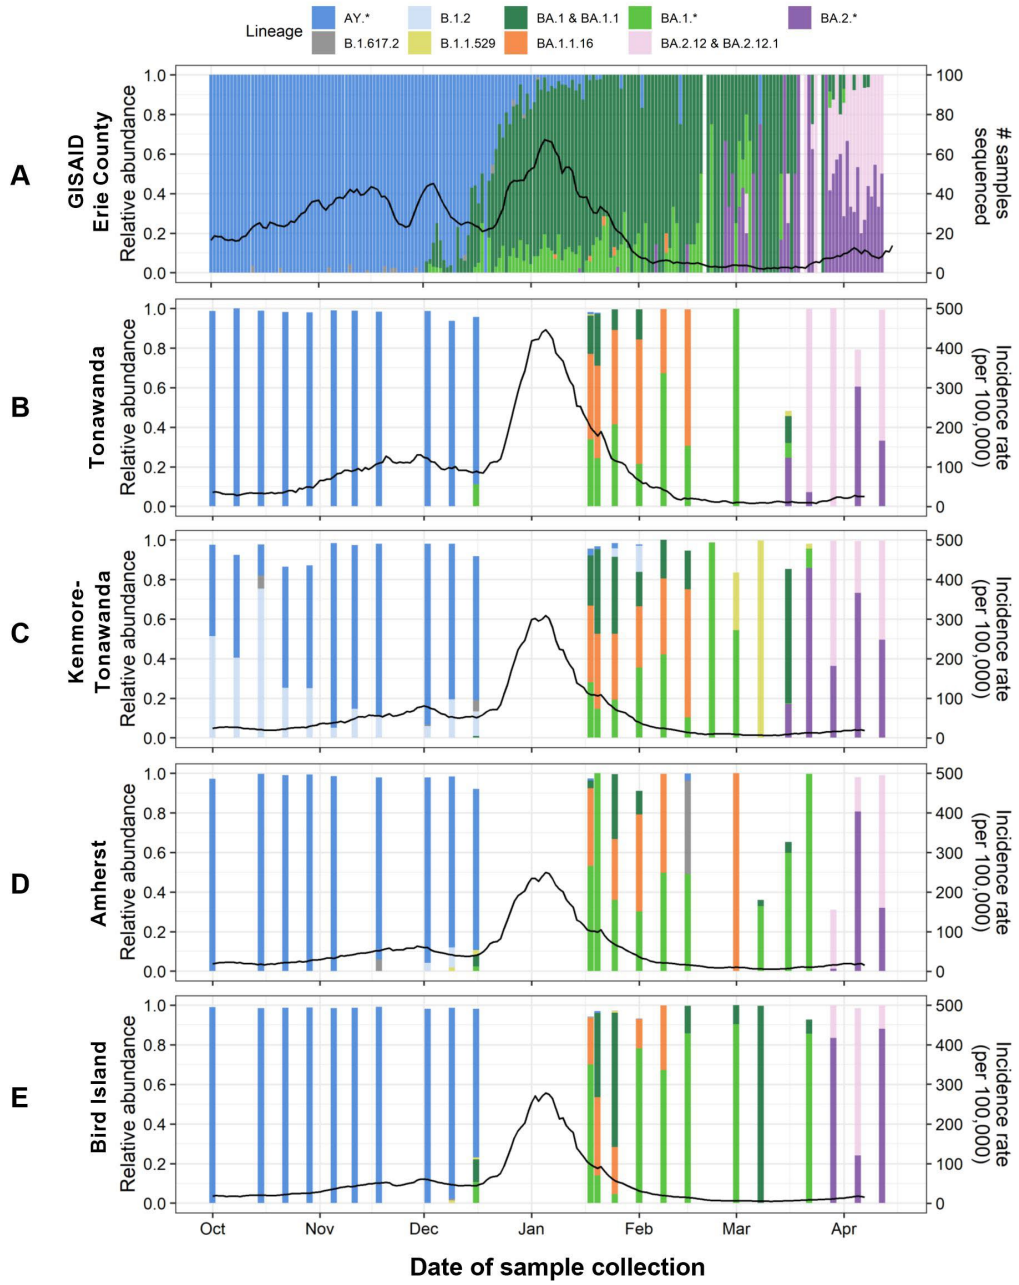

Figure 2. Distributions of dominant SARS-CoV-2 lineages estimated from Erie County clinical data deposited on GISAID (A) and wastewater sequencing data (B–E) during the sampling periods. The solid black lines represent the rolling 7-day average numbers of clinical samples collected for sequencing (A) and COVID-19 incidence rates (cases per 100 000 people) in each sewershed (B–E).

273

274 **Early detection of variants in wastewater**

275 The values of early detection of SARS-CoV-2 variants in wastewater depend on the delays
276 in clinical analysis.[41] The workflow optimization for a quick turnaround of WGS analysis is
277 beyond the scope of this study. Here, we only compare the detection of emerging SARS-CoV-2
278 variants based on the date of collection for both wastewater and patient samples.

279 The Omicron BA.1 was first identified in Amherst and Bird Island wastewater with a
280 relative abundance of 1-2% in the second week of December, which is ~1 week later than the
281 patient-derived samples (**Figure 3**). The detection of Omicron BA.2 from wastewater samples in
282 March was similarly delayed (**Figure 3**). Note that some BA.2 patient-derived samples were
283 collected in January and February, but there was no Omicron BA.2 outbreak until March. The poor
284 detection of Omicron BA.2 in wastewater may be attributable to the relatively low coverage of the
285 SARS-CoV-2 genome from wastewater during mid-February and early March (<65%; Table S3).
286 Nevertheless, our findings suggest that wastewater is a relevant proxy for patient samples.
287 Wastewater WGS should be considered in the face of practical delays in clinical sequencing for
288 early detection of variants.

289 We found that RT-qPCR assays were more sensitive than wastewater WGS for detecting
290 Omicron BA.1-specific mutations, but wastewater WGS was more sensitive for Omicron BA.2-
291 specific mutations (**Table S4**). However, RT-qPCR assays are less sensitive than digital PCR
292 assays,[42] which were reported to detect variant-specific mutations earlier than genetic sequencing.[9]
293 Interestingly, our RT-qPCR assays detected S:delH69/V70 mutations (for Omicron BA.1) in the
294 Kenmore-Tonawanda wastewater samples collected in October 2021. Although WGS also
295 detected these mutations, other Omicron-specific mutations in the S gene (Q493R and Q498R)

were not detected at the time. Wastewater WGS may thus be more precise than PCR assays for early detection of SARS-CoV-2 variants.

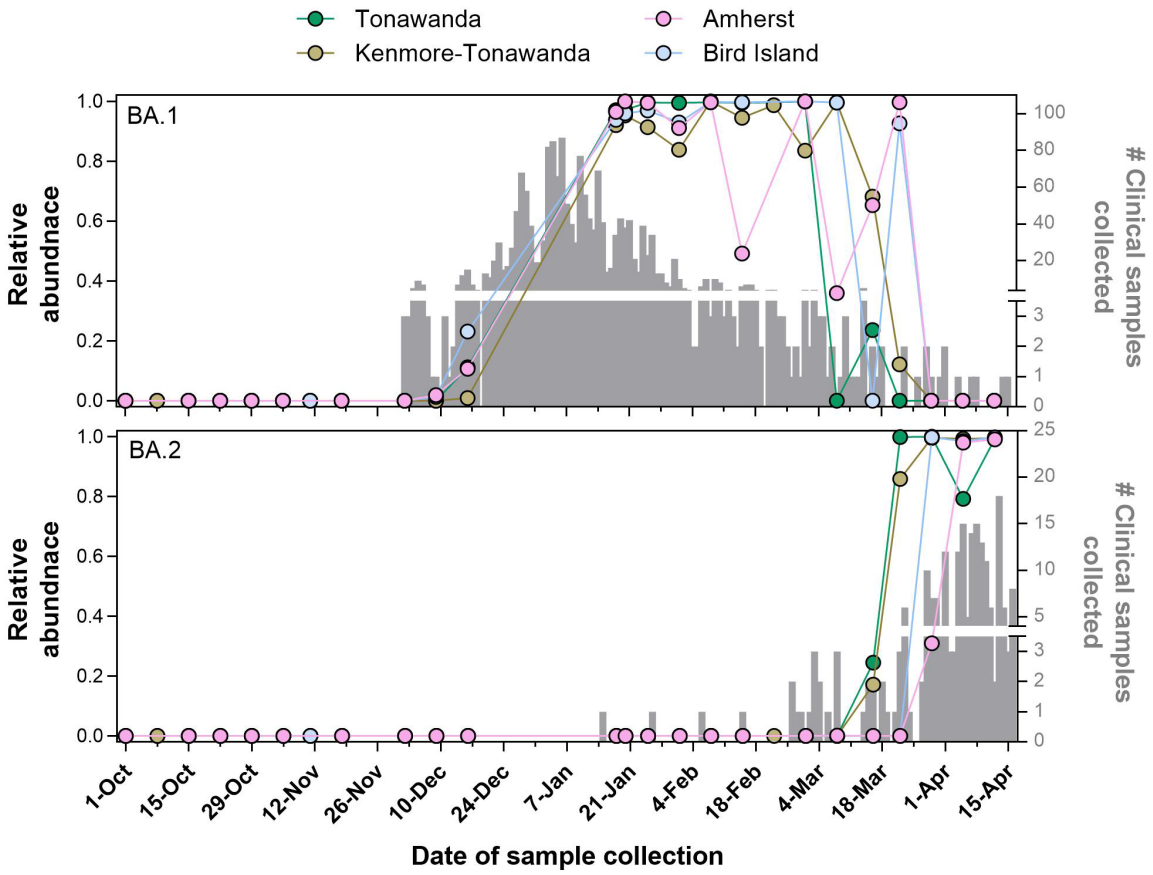

Figure 3. Detection of Omicron BA.1 and BA.2 in wastewater and clinical samples. The relative abundance of Omicron was predicted by Freyja pipeline with the wastewater sequencing data filtered at 50× depth. The relative abundance of BA.1 (top) is the sum of relative abundances of B.1.1.529, BA.1, BA.1.1, and other BA.1.*. The relative abundance of BA.2 (bottom) comprises BA.2.12, BA.2.12.1, and other BA.2.*. The number of clinical samples collected for sequencing was counted on every collection date.

306 **Environmental implications**

307 Our research demonstrates that tangential-flow filtration to concentrate viruses from
308 wastewater samples enables extraction of nucleic acids of high-enough quality for stable
309 performance of SARS-CoV-2 WGS. Complete or near-complete genomes at a depth of 10× were
310 sequenced from 68% (64/94) of the wastewater samples. Moreover, the tangential-flow filtration
311 method improves the WGS success at lower COVID-19 incidence rates. Our results report a 0.9
312 probability of WGS success when the COVID-19 incidence rate exceeded 33/100 000 persons.
313 Furthermore, WGS of SARS-CoV-2 in wastewater revealed lineages underrepresented or not
314 detected from patient samples. Future studies are needed to advance wastewater WGS data
315 interpretation and streamline the workflow of wastewater WGS to shorten the turnaround time for
316 early detection.

317 The developed reusable and likely cost-effective tangential-flow filtration method is
318 readily applicable to other sequencing assays that requires high-quality viral nucleic acids from
319 wastewater. Given the flexibility of concentrating large volumes of wastewater, the tangential-
320 flow filtration system can be further optimized for genomic surveillance of low-abundance viruses
321 in wastewater.

322

341 **ACKNOWLEDGEMENTS**

342 This work was funded by Erie County Department of Health (ECDOH) award 91287 to Y.Y. and
343 I.M.B. and award 91279 to J.A.S.. We thank undergraduate students Vicky Huang and Danya
344 Hanin for processing the wastewater samples in the lab. We also thank Joseph L. Fiegl for
345 coordinating the wastewater sample collection. The GISAID data used in the manuscript
346 (Identifier: EPI_SET_220906wr) is composed of 4952 individual genome sequences published in
347 GISAID's EpiCoV database. To view the contributors of each individual sequence with details,
348 visit doi.org/10.55876/gis8.220906wr. Most of the samples (4653/4952) were sequenced at the
349 University at Buffalo. We are grateful for the sequencing work of scientists and healthcare
350 professionals who generated the remaining sequences from the region and made them publicly
351 accessible through GISAID.
