Abstract

Background: Most of neonatal deaths occur among low birth weight infants. However, in resource-limited settings, these infants are commonly discharged early which further exposes them to mortality. This study aimed at determining the proportion and predictors of mortality among low birth weight neonates that are discharged from Mulago National Referral Hospital in Uganda.

Methods: This was a prospective cohort study of 220 low birth weight neonates discharged from a Special Care Baby Unit at Mulago National Referral Hospital. These were followed up to 28 completed days of life, or death, whichever occurred first. Proportions were used to express mortality. To determine the predictors of mortality, Cox hazards regression was performed.

Results: Of the 220 enrolled participants, 216 (98.1%) completed the follow-up. The mean gestational age of study participants was 34 ±3 weeks. The median weight at discharge was 1,650g (IQR: 1,315g -1,922g) and 46.1% were small for gestational age. During follow-up, 14/216 (6.5%) of neonates died. Mortality was highest (7/34, 20.6%) among neonates with discharge weights less than 1,200g. The causes of death included presumed neonatal sepsis (10/14, 71.4%), suspected aspiration pneumonia (2/14, 14.3%), and suspected cot death (2/14, 14.3%). The median time to death after discharge was 11 days (range 3-16 days). The predictors of mortality were a discharge weight of less than 1,200g (adj HR: 23.47, p <0.001), a 5-minute Apgar score of less than 7 (adj HR: 4.25, p = 0.016), and a diagnosis of neonatal sepsis during admission (adj HR: 7.93, p = 0.009).

Conclusion: Post-discharge mortality among low birth weight neonates in Uganda is high. A discharge weight of less than 1,200g may be considered unsafe among neonates. Caregiver education about neonatal danger signs, and measures to prevent sepsis, aspiration, and cot death should be emphasized before discharge and during follow-up visits.

Keywords: *Mortality, low birth weight, neonate, post-discharge.*

Introduction

Worldwide, an estimated 20 million infants are born with low birth weight (LBW) annually. The majority of these births (96.5%) occur in low and middle-income countries (LMICs)(1). Low birth weight contributes 60-80% of all neonatal deaths worldwide. Preterm birth, which is commonly associated with LBW is the most common direct cause of neonatal mortality(3). Low birth weight neonates are at increased odds of death compared to their heavier counterparts(4) and LBW is considered the single most important predictor of infant mortality (5).

The World Health Organization (WHO) developed discharge criteria for LBW infants(6). However, this has been difficult to adhere to in resource-limited settings like Uganda with an over-stretched healthcare system and an estimated 10% of births have LBW(2).

In Uganda, many neonatal units lack proper Kangaroo Mother Care (KMC) facilities(7,8), yet this is known to improve the survival of LBW infants (9).

Previous studies have assessed the morbidity and mortality of LBW infants after early discharge. Nonetheless, these mainly focused on Very Low Birth Weight (VLBW) infants and without the description of post-discharge neonatal mortality (10–12). Post-discharge outcomes of LBW neonates are largely unknown.

In our setting, LBW infants are discharged from the Special Care Baby Unit (SCBU) once stable (off antibiotics and oxygen, with stable body temperature in a cot). In addition, they should be able to tolerate 10ml per feed of expressed breastmilk by cup or tube, regardless of body weight or weight growth velocity. These babies are followed up weekly until they attain a body weight of 2500g. This practice may serve to reduce pressure on available limited resources, but its safety has not been assessed. This study aimed at determining the proportion of LBW neonates that die after discharge from the SCBU, and the predictors of mortality.

Methods and materials

Study setting

This was a prospective cohort study conducted at the SCBU of Mulago National Referral Hospital from 8th November 2018 to 28th January 2019. This SCBU was a level II neonatal unit. On average 4,600 babies are admitted to the unit annually, and 50% of these are low birth weight neonates.

The SCBU had an official bed capacity of 50 with 13 baby cots, 22 incubators, 11 radiant warmers, and 4 beds, but it often houses over 100 babies. It had term and preterm baby sections but with no KMC wing. The unit was run by 4 Paediatricians, 4-6 Paediatrics residents, 2 intern doctors on a rotational basis, and 18 nurses (working in 3 shifts a day).

The care offered included the provision of warmth (incubators and radiant warmers), phototherapy, and bubble Continuous Positive Airway Pressure (CPAP). Admitted neonates may also receive intravenous fluids (two hourly boluses), intravenous

antibiotics, and nasogastric feeding. Vital signs were intermittently assessed and caregivers feed their babies every two hours under the supervision of the nursing team.

Low birth weight infants are discharged from the SCBU once they are deemed physiologically stable (normal axillary temperature, off oxygen, off intravenous fluids, and apnea-free), tolerating at least 10ml per enteral feed, and gaining weight. The caregiver must demonstrate knowledge and competence in the provision of care to the infant before discharge. On average, 138 LBW neonates are discharged monthly.

After discharge, LBW infants were followed up in the clinic every week until a body weight of 2500g is attained. During clinic visits, growth monitoring, drug refills (Iron and multivitamins), nasogastric tube replacement, and adjustment of feeds were done. Unwell infants were identified and readmitted.

Study population

All neonates discharged from the SCBU with a birth weight of <2500g. Those who were neither reachable physically nor by telephone were excluded from the study.

Sample size

The sample size was estimated using an OpenEpi formula for frequency in a population (13). Since no similar studies were addressing post-discharge mortality among LBW neonates, we assumed a frequency of 50%.

The calculated sample size (n) was 220 with a precision level of 5%.

Data collection procedure

All neonates with birth weight <2500g were identified by a research assistant at discharge. Their parents were then introduced to the study. For neonates who met the inclusion criteria, the research assistant obtained written informed consent from the caregiver/ guardian. Recruitment was conducted daily and consecutively until the desired sample size was achieved.

Recruited neonates received a study identification number and their details were captured in a logbook. Each parent provided 3 phone contacts for purposes of follow-

up. Phone contacts of the principal investigator (PI) and research assistants were shared with parents for them to call in case of any concerns.

Data were captured at discharge and every clinic visit. Study participants were followed up for 28 days. Parents of study participants were contacted by telephone once a week and significant events (death, illness) were registered. Those who missed their scheduled follow-up visits were contacted by phone and requested to bring the neonate for review on the next clinic day. A neonate who missed two consecutive clinic visits and whose parents were not reachable by phone throughout the study period was considered lost to follow-up.

Data management and analysis

Captured data were entered into Epidata version 3.1, checked for accuracy and completeness, and exported to STATA Version 14 for analysis. Continuous variables were summarized using the mean and standard deviation, and median and interquartile ranges for skewed data. Categorical variables were summarized using frequencies and proportions.

The proportion of LBW neonates that died after discharge from the SCU was expressed as a percentage. The numerator was the number of babies that died within the first 28 days of life and the denominator was the total number of LBW neonates recruited into the study. Chi-square and Fisher's exact tests were used to compare the proportion of LBW neonates that died after discharge from the SCU by their baseline characteristics.

Student-t and Wilcoxon rank sum tests were used to compare means and median respectively of the continuous variables of participants that died and those that were alive after 28 completed days of life. To determine the predictors of mortality, relative death rates (Hazard Ratios) were obtained using simple Cox proportional hazards regression.

Variables that achieved a level of significance of ≤0.05 were then included in a multivariable Cox proportional hazards model. Backward elimination was used to build a model of best fit. The level of significance was set at ≤0.05 and a confidence interval of

95% was used. Kaplan Meier curves were used to compare survival across gender, gestation age at birth, and birth weight.

Results

Of the 243 LBW neonates identified for potential recruitment into the study, 5 did not consent to the study, and 18 did not have phone contact. Therefore, a total of 220 (representing 90.5%) neonates were enrolled in the study. Of these, 216 completed follow-up. The mean gestational age at birth was 34 ±3 weeks, and the median weight at discharge was 1650g (IQR 1315-1922 grams). All four neonates who were lost to follow-up had discharge weight >2000g.

The median length of hospital stay of study participants was 5 days (IQR 3-8 days). The majority of the study participants (134/216, 62%) were fully breastfeeding, and the rest were breastfeeding and receiving top-up feeds through a nasogastric tube. Five study participants had confirmed neonatal sepsis during admission, and they had completed treatment before discharge (**Table 1** shows the details of the characteristics of the study participants)

Note: *p*- values are based on Pearson's Chi-square test (c) and Fisher's exact test (f).

During follow-up, 14/216 (6.4%) neonates died. Of these, 8 occurred from home, 5 occurred at a health facility, and 1 occurred on the way to the hospital. The circumstances surrounding each death were established by contacting the primary caregiver by phone. The likely causes of death included neonatal sepsis (71.4%), aspiration pneumonia (14.3%), and cot death (14.3%). The median time to death after discharge was 11 days (range 3-16 days).

The proportion of neonates that died was highest among those with discharge weight <1200g (20.6%) and gestational age at birth <30 weeks (28.6%).

Figure 1 shows that the overall survival probability was 93.5% and the greatest drop in survival probability occurred in the first week after discharge. The median survival time had not been reached by the time the study closed meaning that survival was sustained above 50% throughout the study period. Survival was compared according to birth

weight. **Figure 2** shows that survival probability was highest among study participants with birth weight >2,000g. Notably, survival dropped with reducing birth weight.

The neonates who died had a lower median body weight at birth, discharge, and first follow-up visit, compared to those who survived. In both groups, the median discharge weight was lower than the birth weight. Among those who died, the median body weight at the first follow-up visit was lower than the median weight at discharge as shown in **Figure 3**.

Predictors of mortality were assessed at bivariate and multivariate levels of analysis. Discharge weight <1200g was associated with a 23.5-fold increase in the risk of death compared to babies of discharge weight greater than 1,500g (p<0.001). The neonates who posted a 5-minute Apgar of <7 were 4.42 times more likely to die compared to those with a 5-minute Apgar of 7 and above (p=0.016). Similarly, having a diagnosis of neonatal sepsis at admission was significantly associated with mortality compared with those that did not have such a diagnosis (adj HR = 7.93, p = 0.009). Notably, none of the maternal sociodemographic characteristics was significantly associated with mortality. The details of the unadjusted and adjusted hazard ratios are shown in **Table 2**.

Discussion

In this study, we observed a post-discharge neonatal mortality of 6.5%. Mortality was highest among neonates delivered before 30 weeks of gestation (28.6%), those with birth weight <1500g (18.5%), and discharge weight <1200g (20.6%). Most of the deaths occurred at home and were due to possible neonatal sepsis.

The post-discharge mortality we observed at the referral hospital was lower than what was previously reported in two other similar settings. In Bangladesh, a study by Yasmin et al, 2001 found a mortality of 13.3% (4), while in Malawi, Blencove et al, 2009 found a mortality of 12.4% (14). The discrepancies may be explained by the differences in engagement between the healthcare facilities and the caregivers post-discharge. The level of mortality was however comparable to what Vazirinejad et al, 2012 found (5.4%) in Iran(15), and what Kibona et al found in Tanzania (16).

In all these studies, however, mortality was similarly higher among neonates with birth weights <1500g and those with gestational age at birth <30 weeks. The lower mortality observed in our study and Tanzania may be due to advances in neonatal care over the last 10 years since the other two studies were carried out. The higher mortality among those with birth weight <1500g, gestational age at birth <30 weeks, or discharge weight <1200g may be explained by immature oromotor coordination, poor homeostatic control among neonates with lower birth weight and lower gestational age at birth(17), and increased risk of sepsis in the same age group.

In our study, 3 in 5 LBW neonates who died had possible neonatal sepsis. This is comparable to the findings by Abdallah et al (10). It is not surprising because neonatal sepsis accounts for about 1 in 5 neonatal deaths in Uganda (18) and it is a significant contributor to neonatal deaths in most low and middle-income countries(19). Studies have shown that low birth weight is a risk factor for neonatal sepsis(20–22). Disease progression is fast and deaths occur rapidly. Indeed, our study found that the majority of the deaths occurred at home before parents had taken action to save their infants.

212 These findings are similar to what was found in Malawi (14). In part, this could reflect
213 inadequacies by parents to recognize danger signs in neonates and seek care promptly
214 as has been documented in Southwestern Uganda(23). On the other hand, this may be
215 explained by the fact that caregivers who think an infant is likely to die may be less likely
216 to seek urgent care, especially if the infant is fragile and small(24).

217 Predictors of mortality in this study were; discharge weight <1200g, 5- minute Apgar
218 score <7, and a diagnosis of neonatal sepsis during admission. Low birth weight
219 neonates with discharge weight <1200g were 23 times more likely to die compared to
220 heavier neonates. These results are comparable to what Abdallah et al, and Blencowe
221 et al found (10,14); that the risk of post-discharge mortality increases with decreasing
222 weight at discharge. This could be because smaller neonates, especially those with
223 weight <1500g are more likely to be preterm(1), and have not yet attained oromotor
224 maturity and appropriate homeostatic control. These neonates are therefore at greater
225 risk of complications like hypothermia, hypoglycemia, and aspiration. They are also
226 more likely to have immature immune systems (22). To compound this, they are likely to
227 have been born before the maximal transplacental transfer of antibodies from the
228 mother, which occurs in the last 8 weeks of gestation (25). They are therefore at
229 increased risk of infections, hence mortality.

230 Low birth weight neonates with an Apgar score <7 at 5 minutes were 4 times more likely
231 to die compared to those with an Apgar score ≥7. These results are in keeping with
232 what Abdullah et al found in Bangladesh, what a systematic review by Ehrestein found,
233 and what Cnattingius et al found in Sweden; that an Apgar score of <7 at 5 minutes was
234 associated with an increased risk of mortality among LBW neonates (26–28). This may
235 be due to complications of perinatal asphyxia like intraventricular hemorrhage, acute
236 kidney injury, and hypoxic ischaemic encephalopathy. The association between
237 prematurity and low Apgar score (29) may also explain the increased risk of mortality
238 among these neonates.

239 Neonates who had sepsis during admission were 8 times more likely to die after
240 discharge compared to those without this diagnosis. Neonatal sepsis is one of the

major causes of neonatal mortality worldwide (30). The increased likelihood of post-discharge mortality among LBW neonates treated for neonatal sepsis during admission could be a reflection of the persistence of some modifiable and non-modifiable risk factors of neonatal sepsis, like poor caregiver hygiene practices and prematurity. These neonates may therefore be at risk of re-infection and death even after discharge.

Strengths and limitations of the study

This was the first study in Uganda to assess mortality and its predictors among LBW neonates following discharge from the SCBU. The prospective cohort study design used for this study allowed us to establish a temporal association between mortality and its predictors. The study was carried out at a tertiary care facility that receives many referrals. This may have caused selection bias. We relied on clinical symptoms identified and reported by caregivers to ascertain the possible causes of death.

Conclusion

Neonatal mortality of 6.5% among low birth weight infants discharged from the National Referral Hospital is high. The predictors of mortality include discharge weight <1200g, a 5-minute Apgar score of <7, and a diagnosis of neonatal sepsis during admission. Most of the deaths occurred from home, in the first week after discharge, and were due to possible neonatal sepsis.

Improving survival of LBW neonates especially those with Apgar score <7 at 5 minutes, discharge weight <1200g, and /or have had sepsis during hospitalization requires intensive follow-up and care. There is a need to amend the guidelines for the discharge of LBW neonates so that they are discharged with weights >1200. Caregiver education on feeding, prevention of neonatal sepsis, early recognition of danger signs in neonates, and prompt care-seeking should be intensified.

Declarations

Ethical approval and consent to participate

This study protocol was subjected to approval by the Makerere University School of Medicine Research Ethics Committee. The investigators ensured that caregivers (parents or guardians) of study participants were given full and adequate oral and written information about the nature, purpose, possible risks, and benefits of the study. They were given adequate opportunities to ask questions and allowed time to consider the information provided voluntarily. Written consent was obtained from caregivers before conducting this study. Participants in this database were identified by their unique enrollment numbers. Only the PI had access to the participant identification list, which included their unique codes, full names, phone numbers and address.

Consent for publication

Not applicable.
