Abstract

Background

We aimed to describe the prevalence of exposure to traumatic events and post-traumatic stress disorder (PTSD) in pregnant women attending antenatal care (ANC) in rural Ethiopia. We hypothesised that antenatal PTSD symptoms would be associated with previous obstetric complications and intimate partner violence (IPV) and impact negatively on women´s satisfaction with ANC.

Methods

The design was a facility-based cross-sectional study in primary health centres providing ANC in southern Ethiopia. Trauma events were assessed using the Life Events Checklist (LEC) and PTSD checklist for DSM-5 (PCL-5). Previous obstetric complications were extracted from clinical records. IPV was measured using the 'Non-Graphic Language' screening test and ANC satisfaction was measured using a locally validated adapted version of the Mental Health Service Satisfaction Scale. Generalized linear mixed-effects regression models were used to calculate prevalence ratios between PTSD, IPV and ANC satisfaction.

Results

Out of 2079 interviewed women, 52.3% (n=1,087) reported one or more traumatic life events on the LEC. Physical assault was the most common traumatic event experienced (n=485; 23.3%) and witnessed (n=1,176; 56.6%) but only 289 (13.9%) screened positive for IPV. One hundred and six women (5.1%) met DSM-5 criteria for PTSD. Women meeting diagnostic criteria for PTSD had five times increased prevalence of IPV in their current pregnancy [prevalence ratio (PR) 4.34 95%CI 3.01-6.30; p<0.001]. Only twenty-six women had a record of previous obstetric complications (0.01%). Overall, women with PTSD reported less satisfaction with antenatal care.

Conclusions

Despite high exposure to traumatic life events, particularly physical violence, among pregnant women attending ANC in Southern Ethiopia, the prevalence of PTSD is relatively low. Previous obstetric complications and IPV were under-reported, relative to known prevalence estimates. Our study highlights the challenges of detection of psychosocial needs in the ANC setting and the need for targeted interventions to support women's disclosure of difficulties in maternity care settings.

Introduction

Despite the high prevalence and adverse impacts of mental health conditions (MHCs) during the perinatal period (from conception up to two years post-partum), maternal health programmes continue to neglect women's mental health needs (1). In low- and middle-income countries (LMICs), it is estimated 1 in 4 women experience depression in the perinatal period (2). The prevalence of perinatal depressive and anxiety symptoms is higher among the most marginalized women, with least access to health and social care (3). Beyond adverse birth outcomes, perinatal MHCs have transgenerational effects, negatively impacting children's health and development (4). Inadequate recognition and low availability of treatment of perinatal MHCs in LMICs results in women remaining undiagnosed and untreated, impacting their quality of life and the physical and emotional health of their children and families (5).

Most research on perinatal MHCs in Africa has focused on common mental disorders (CMDs), namely depressive and anxiety disorders (6). Little is known about the prevalence of perinatal post-traumatic stress disorder (PTSD) in LMICs and its consequences for women's health and future pregnancies. A systematic review of studies mostly conducted in high income countries (HICs), reported PTSD prevalence of 3.3% antenatally and 4.0% postpartum (7). However, the prevalence of PTSD was higher in women with a history of childhood maltreatment: 18.9% antenatally and 18.5%

postpartum (7). Antenatal PTSD has been reported following traumatic life events such as accidents, interpersonal violence and natural disasters, while birth trauma is a common precipitant for postpartum PTSD (8). Disrespectful and abusive care during childbirth is widespread in Ethiopia (9), as in other countries. In HICs, there is growing awareness of the needs of women exposed to trauma, the potential for re-traumatisation in maternity care and the requirement for therapeutic relationships and trauma-informed care (10). Obstetric complications and IPV are commoner among women in LMICs (11) but few studies have investigated the associations between trauma exposure, PTSD, and ANC satisfaction among pregnant women in low resource settings. There is growing evidence from both HICs and LMICs that person-centered maternity care, which is respectful and responsive, supports women´s autonomy and engages the women in their care leads to improved outcomes (12).

In this study we aimed to describe the prevalence of exposure to traumatic events and PTSD symptoms in pregnant women attending ANC in rural Ethiopia and their associations with previous obstetric complications, IPV and ANC satisfaction. We hypothesised that antenatal PTSD symptoms would be associated with previous obstetric complications and current IPV and would impact negatively on women´s satisfaction with antenatal care received.

Materials and Methods

Study Design

We conducted secondary analysis of data collected in a facility-based cross-sectional study that formed part of a larger study (ASSET) of health system strengthening in sub-Saharan Africa (13). ASSET was a multi-country consortium in Ethiopia, Sierra Leone, South Africa, and Zimbabwe which

138 aimed to improve access to high quality care across three health care platforms: integrated
139 continuing care for non-communicable diseases including mental health conditions (NCD/MH),
140 maternal and newborn care, and surgical care. The data for this analysis was part of the maternal
141 and newborn care platform in Ethiopia (14)

142

143 Study Setting

144 The study was conducted in eight purposively selected health centres in Meskan and Sodo districts,
145 in the Gurage Zone of the Southern Nations, Nationalities and People's Region (SNNPR) of Ethiopia,
146 recently renamed Central Ethiopia Regional State. According to census projections, in 2019 SNNPR
147 had a total population of 20.1 million people, of whom 52.7% were women aged 15-49 years. The
148 median age in the region is 20 years, 84.3% of the population live in rural areas and the total fertility
149 rate is 3.8 births per woman (15).

150

151 Study Population

152 A total of 2079 pregnant women attending health centers consecutively for ANC, who were able to
153 converse in Amharic and provide written informed consent, were included in this study. Acutely ill
154 women who required emergency medical attention were excluded. Data collection took place from
155 18th July 2019 to 9th January 2020. Women were reimbursed the equivalent of $2 for their time: a
156 locally appropriate fee.

157

158 Data Collection

159 Data collection was carried out in a private room within the health facility. All data collectors were
160 female and comprised both lay data collectors (with a minimum of high school education) and
161 clinical data collectors (with a minimum qualification of a diploma in nursing). Data were collected

162 with electronic tablets using Open Data Kit (ODK) software (16). Trained lay data collectors
163 administered fully structured questionnaires. Research nurses extracted information from medical
164 records for each woman using a bespoke template developed for the study(14).

165

166 Measures

167

168 Clinical Characteristics of pregnancy

169 Data on clinical characteristics of the current and any past pregnancies were collected from clinical
170 records using structured forms. Our exposure of interest was previous obstetric complications,
171 defined as one or more of the following during a previous pregnancy or delivery:
172 spontaneous/induced abortion, ectopic pregnancy/ ruptured ectopic pregnancy, hospital admission
173 for pre-eclampsia/ eclampsia, pre-term labour, intra-uterine foetal death, obstructed labour; fistula,
174 Instrumental delivery, delivery by Caesarean section, postpartum haemorrhage, previous baby with
175 a congenital anomaly, and previous baby born weighing less than 2500g or more than 4500g

176

177 Trauma exposure and symptoms

178 Exposure to traumatic events and trauma symptoms were assessed using the Life Events Checklist
179 (LEC) (17) and PTSD checklist for DSM-5 (PCL-5)(18), translated into Amharic and adapted for the
180 rural Ethiopia context(19). In the LEC, women were asked if they had experienced traumatic life
181 events, witnessed them or learned about them through social interactions or their occupation. The
182 PCL-5 checklist consists of 20 statements rated from “not at all” (score 0) to “extremely” (score 4).
183 Each item rated 2 ("moderately") or higher was considered endorsement of a symptom. PCL-5
184 divides PTSD symptoms, with questions 1-5 reflecting criterion B (intrusion) symptoms, questions 6-

185 7 reflecting criterion C (avoidance) symptoms, questions 8-14 reflecting criterion D (negative
186 alterations in cognitions and mood) symptoms, and questions 15-20 reflecting criterion E (alterations
187 in arousal and reactivity) symptoms. Women met DSM-5 criteria for PTSD if they scored 31 or above
188 on PCL-5 and endorsed at least one criterion B, C, D or E symptom.

189

190 Depressive and Anxiety Symptoms

191 Depressive symptoms were measured using the Patient Health Questionnaire (PHQ-9). In a previous
192 validation study of PHQ-9 (20) in health centres in the study area, a cut-off of 5 or more provided the
193 best discrimination between people with and without major depressive disorder but had low
194 positive predictive value (<25%). We categorised cases as 'probable depression' if the individual
195 scored 5 or more on the PHQ-9 and reported that it was very difficult or extremely difficult for them
196 to function in daily life. This accorded with international diagnostic criteria for depressive disorder
197 which require impaired functioning alongside symptoms. Anxiety symptoms were measured using
198 the generalised anxiety disorder scale (GAD-7)(21). Women were categorised as having low anxiety
199 symptoms if they scored 5-9, moderate anxiety symptoms if they scored 10-14 and severe anxiety
200 symptoms if they scored 15 or above.

201

202 Intimate Partner Violence (IPV)

203 IPV was measured using the 'non-graphic language' (NGL) IPV screening test (22) based on the
204 Conflict Tactics Scale-Revised (23). The NGL scale comprises 5 questions on experience of physical or
205 psychological violence with an intimate partner. It was previously found to be acceptable in the study
206 population, where it had convergent validity with the more extensive World Health Organization
207 (WHO) IPV questionnaire (24). We categorised participants scoring 2 or more on questions 1

208 (working out arguments), 3 (partner treatment) or 4 (feeling safe) as experiencing marital discord
209 and possible IPV.

210

211 Service satisfaction

212 Satisfaction with ANC was measured using the adapted version of the Mental Health Service
213 Satisfaction scale, validated for Ethiopian health centres and used in the ASSET diagnostic phase
214 (25). The modified MHSS scale had 21 items, each with four Likert response categories (1: strongly
215 disagree, 2: disagree, 3: agree and 4: strongly agree). Most items assessed generic aspects of
216 outpatient care relevant to the context, such as health worker communication, waiting times,
217 privacy, usefulness of care, cleanliness of the facility. For this study we analysed total satisfaction
218 scores and responses to all specific questions. We dichotomised results for individual items into
219 satisfied (answering 'agree' or 'strongly agree') and non-satisfied (answering 'disagree' or 'strongly
220 disagree').

221

222 Covariates

223 Sociodemographic characteristics including age, marital status, place of residence, educational level
224 and religion was gathered using structured measures in an interview format by the same lay data
225 collectors. Social support was assessed using the Oslo Social Support scale used previously in the
226 study setting and found to have convergent validity (26).

227

228 Ethical Considerations

229 We obtained ethical approval from the Addis Ababa University College of Health Sciences
230 Institutional Review Board (Reference number: 028/18/Psy) and King's College London Research

Ethics Committee (Reference number: HR-17/18-6570). The study was conducted according to the Declaration of Helsinki. All participants provided written informed consent.

Analysis Plan

We used descriptive statistics to calculate socio-demographic, clinical characteristics and satisfaction scores for the total sample and those participants meeting criteria for PTSD. We used Chi-squared and Fisher exact tests to compare socio-demographic characteristics and previous obstetric complications in those with and without PTSD. To account for the effect of the number of data collection days in each health centre and average ANC attendance per health centre per day (calculated over a 6-month period), we included these variables and used health centre as the clustering variable in all the following regression analyses. We used Poisson mixed-effect regression to calculate prevalence ratios of co-morbid depression and anxiety in participants meeting criteria for PTSD. We used a univariate and multivariate Poisson mixed-effects regression model, adjusted for *a priori* identified confounders: parity, education, place of residence and age, to calculate prevalence ratios between PTSD and IPV. We performed a univariate and multivariate linear mixed-effects regression test adjusted for the same confounders, to test the association between PTSD detection and ANC satisfaction. We conducted a univariate and multivariate logistic mixed-effects regression model for the association between PTSD and dichotomised satisfaction on each MHSS item. We tested differences in responses to each MHSS item between those with and without PTSD using Fisher exact tests.

Results

Socio-demographic characteristics

255

256 See Table 1. Out of 2079 participants, 1,024 (49.3%) were attending their first ANC appointment.
257 Participants' mean age was 26.0 years (standard deviation (SD) 4.9; range: 18 to 50 years). The
258 majority of women (n=2013; 96.8%) were married and had some formal education (n=1,468; 70.6%,
259 see Table 1).

[1] Using DSM-5 criteria

Current and Previous Pregnancy Characteristics

Most participants were in their second trimester (54.3%, n=1,120) of a wanted pregnancy (78.5%, n=1,632). Median parity was 1 (interquartile range: 0-3); for 28.7% of women (n=595) this was their first pregnancy. A history of co-morbid physical health problems was documented in the clinical records of four (n=4) participants.

A total of 26 (0.01%) women had previous obstetric complications documented in their clinical records: recurrent miscarriage (n=15), stillbirth (n=12), previous Caesarean section (n=4), hospitalisation for pre-eclampsia/eclampsia (n=2), fistula (n=1), and previous post-partum haemorrhage (n=1). Ectopic pregnancy, assisted delivery, previous baby with a congenital anomaly, and previous baby born weighing less than 2500g or more than 4500g were not documented for any participants.

Trauma exposure and PTSD symptoms

278 A total of 1,087 (52.3%) women reported one or more traumatic life events on the LEC (range: 0 to
279 10; see Figure1). Twenty-seven percent of women (n=551) reported one traumatic event and 13.2%
280 (n=275) reported three or more traumatic life events. Physical assault was the most common
281 traumatic event experienced (n=485; 23.3%) and witnessed (n=1,176; 56.6%), whereas sexual
282 violence was infrequently reported (2.7% (n=57) reported sexual assault and 1.9%(n=40) reported
283 other unwanted sexual experiences; see Table 2). Direct exposure to armed combat was reported by
284 five (0.2%) women and witnessed by 90 (4.3%). Experience of a life-threatening injury or illness or
285 severe suffering were reported by 567 women (27.3%). One hundred and six women (5.1%) met
286 DSM-5 criteria for PTSD ('probable PTSD').

287

288

289

290

291

292

293 **Table 2. Types of Traumatic Life Events directly experienced and witnessed by women.**

Life event	Directly experienced (n, %)	Witnessed (n, %)
Physical assault	485 (23.3%)	1,176 (56.6%)
Life threatening injury/illness	396 (19.1%)	846 (40.7%)
Natural Disaster	221 (10.6%)	556 (26.7%)
Fire	182 (8.8%)	809 (38.9%)
Other very stressful event	175 (8.4%)	288 (13.8%)
Severe human suffering	171 (8.2%)	646 (31.1%)
Motor vehicle accident	99 (4.8%)	520 (25.0%)
Captivity	85 (4.1%)	391 (18.8%)
Sudden unexpected death of loved one	80 (3.8%)	661 (31.8%)
Other serious accident	64 (3.1%)	231 (11.1%)
Sexual assault	57 (2.7%)	110 (5.3%)
Assault with a weapon	51 (2.5%)	312 (15.0%)
Sudden violent death	50 (2.4%)	495 (23.8%)
Other unwanted sexual experience	40 (1.9%)	58 (2.8%)
Caused serious injury/ death of another	18 (0.9%)	155 (7.5%)

Exposure to toxic substance	11 (0.5%)	41 (2.0%)
Combat	5 (0.2%)	90 (4.3%)

There were no significant differences in education level, residence, marital status and parity between women with and without probable PTSD (see Table 1). Women meeting diagnostic criteria for PTSD were more likely to be aged 25 to 34 years old rather than younger and to report lower levels of social support than women not meeting criteria for PTSD.

Forty-four percent (n=47) of those with probable PTSD also experienced moderate to severe anxiety symptoms compared to 1.5% (n=29) of women without PTSD. Nearly a quarter of participants with probable PTSD experienced co-morbid probable depression (n=25; 23.6%), compared to 4.3% (n=85) of those without PTSD. Women with probable PTSD were significantly more likely to experience co-morbid probable depression (prevalence ratio (PR): 5.50, 95% CI: 3.99-7.59, p<0.001) and severe anxiety symptoms (PR: 20.80, 95% CI: 13.87-31.20, p<0.001) in unadjusted analyses.

Associations between previous obstetric complications and trauma symptoms

Very few participants' clinical records documented obstetric complications in a previous pregnancy (n=24; 0.01 % in women not meeting criteria for PTSD and n=2 in women meeting criteria for PTSD); the association was not statistically significant (p=0.502).

Association between trauma symptoms and IPV

313 A larger proportion of women with probable PTSD screened positive for probable IPV (41.5%; n=44)
314 compared to women without PTSD (n=245; 12.4%). Women meeting diagnostic criteria for PTSD had
315 four times greater risk of reporting IPV in their current pregnancy in both the unadjusted model (PR:
316 4.30, 95% CI: 2.25-8.21, p<0.001) and after adjustment for parity, age, education and area of
317 residence (PR 4.20 95%CI 2.05- 8.61; p<0.001). Of those screening positive for IPV in the total
318 sample (n=289, 13.9%), 133 (46.0%) reported directly experiencing physical assault and 19 (6.6%)
319 sexual assault.

320

321 **Association between trauma symptom and service satisfaction**

322 The mean total satisfaction with ANC score was 57.59 (SD=8.42) for women without probable PTSD
323 and 56.40 (SD=6.27) in women with probable PTSD. The mean difference was 1.19 (95% CI: -0.44 to -
324 2.82) which when accounting for clustering by health center was found to be significant in both
325 unadjusted analyses (regression coefficient: -0.73 (95% CI: -1.35 - -0.11, p=0.022) and after
326 adjustment for parity, age, education and area of residence [adjusted regression coefficient (adj RC):
327 -0.73 (95% CI: -1.36 - -0.10, p=0.022] .

328

329 Women meeting criteria for PTSD were more likely to report that ANC waiting times were
330 acceptable [adjusted Odds Ratio (adj OR) =2.35, 95% CI: 1.64-3.38, p<0.001)], that their privacy was
331 respected (adj OR =2.94, 95% CI: 1.91-4.52, p<0.001), that their information was kept confidential
332 (adj OR =2.14, 95% CI: 1.61-2.85, p <0.001) and that referral to other services was possible (adj OR
333 =3.64, 95% CI: 1.82-13.00, p=0.047) . Participants with probable PTSD were significantly less likely to
334 report that the health worker involved their family helpfully (adj OR =0.29, 95% CI: 0.12-0.67,
335 p<0.001) and that they can afford to attend the health facility for treatment (adj OR 0.60, 95% CI
336 0.37-0.99, o=0.047); see Table 3). There were significant differences in satisfaction responses

337 between women with and without probable PTSD for all ANC satisfaction items. Women fulfilling

338 criteria for PTSD were more likely to answer “agree” rather than “strongly agree” to most items,

339 despite similar overall satisfaction scores (table 4).

340

Table 3. Logistic mixed-effects regression models of associations between PTSD and ANC satisfaction.

		Probable PTSD (n=106)		Not probable PTSD (n=1,973)		Univariate logistic mixed-effects regression model (Odds ratio (OR) 95% confidence interval (CI)	Multivariate logistic mixed-effects regression model adjusted for parity, age, education and residence Adjusted OR (95%CI)
		Satisfied	Not Satisfied	Satisfied	Not satisfied

Discussion

Our facility-based cross-sectional study identified high levels of exposure to life-threatening injury, illness and suffering but paradoxically a low prevalence of antenatal PTSD (5.1%) (6), similar to previous survey of PTSD symptoms conducted in Nigeria (27). Over half the participants had directly experienced trauma, with physical violence victimisation especially common. Nearly half of those reporting physical violence screened positive for IPV. Very few women disclosed sexual trauma. There may be several reasons for nondisclosure. Stigma associated with sexual assault deters many victim-survivors from speaking about their experiences (28). Sexual discrimination against girls is common in Ethiopia (29) and worldwide. A multiregional study conducted by World Health Organization estimated the prevalence of lifetime sexual violence among women to be 30% (30). In the Ethiopian Demographic and Health Survey (EDHS) 2016, 10% of women aged 15–49 years were reported to have experienced sexual violence (31) Furthermore, previous studies have found that many women and girls in Ethiopia do not disclose their experience of domestic violence (32), despite known high prevalence (33). Reasons include shame, embarrassment and fear of disclosure related consequences. Less than 15% of our sample disclosed IPV, despite the estimated prevalence of antenatal IPV in Ethiopia ranging between 21.0% (34) and 26.1% (35). IPV has been associated with post-partum depressive symptoms in the Ethiopian context (34). Our study found that IPV was significantly associated with antenatal PTSD symptoms.

Among participants who had experienced a previous pregnancy, less than 1% of clinical records documented obstetric complications. This is not consistent with national estimates of around 20% (36). Prolonged labour is the leading cause of major direct obstetric morbidity in Ethiopia, accounting for 23.4%. Hypertensive disorders are the second most frequent cause of major direct maternal morbidity with a prevalence of around 11% (36). Reasons behind low recording of obstetric complications need to be further explored. Women with previous obstetric complications may be

less prepared or less likely to attend ANC in subsequent pregnancies, or feel unable to disclose previous complications to health workers, for example in case it negatively impacts their care. It is also likely health workers may not actively ask about previous complications or do so in a manner that does not promote disclosure. Unfortunately, disrespectful and abusive care during childbirth is widespread in Ethiopia (9), as in other countries. Reported prevalence of disrespect and abuse during childbirth in Ethiopia ranges from 21.1% to 98.9% (9). Qualitative research has described how fear of using health facilities is a common consequence of experiencing disrespectful care (37).

Women with antenatal PTSD showed a lower overall satisfaction with ANC compared to women without antenatal PTSD but paradoxically scored certain aspects of care higher than women without PTSD. Indeed, they endorsed more items regarding respect for their privacy and confidentiality. This finding should be interpreted with caution due to potential for response bias if women believe their answers may influence further care. Women with probable PTSD were less likely than women without probable PTSD to report that the health worker engaged their family helpfully and that they could afford to attend antenatal care. As IPV was more prevalent among participants with probable PTSD, training on sensitive ways to involve family members and ensure women are supported to attend ANC is a particular priority. Women with probable PTSD were less likely to endorse "strongly agree" responses for most aspects of care provided, indicating a systematic difference in reporting and highlighting the need to develop sensitive and validated scales to adequately capture the actual experiences of women accessing care.

Our results highlight the importance of person-centred maternity care to improve outcomes and experience of care for women. Previous studies from LMICs indicate that higher ratings of ANC dignity, respect, and supportiveness are associated with fewer newborn complications and increased willingness to access ANC for future pregnancies (38). The absence of person-centred maternity care has been associated with birth and post-partum complications (39). In 2019, the Federal Ministry of

Health of Ethiopia introduced the Ethiopian Primary Health care Clinical Guidelines (EPHCG) promoting integrated, person-centred and evidence-based care in health centres (40). In order to promote person-centred maternity care, systemic changes are required in tandem with health worker training and supervision. The ASSET team collaborated with the Ministry of Health to adapt training resources in person-centred care for maternal care in Ethiopia(41) Beyond training, services need to empower women with greater understanding of their rights and instil trust to facilitate disclosure of trauma; however, this requires cultural changes at the organisational level, including support and supervision for health workers, manageable caseloads and conductive clinical environments (42). Previous research in South Africa highlighted that efforts to improve detection of mental health conditions and IPV need to occur concurrently with development of pathways for referral and treatment/support for women to be confident their needs will be listened to and acted upon (42).

Despite high levels of high trauma exposure, only a small proportion of women in our sample met criteria for PTSD. Qualitative research is required to explore how women respond to and cope with traumatic life events in this context. While perinatal depression is widely researched, less is known about the impacts of PTSD and trauma exposure on woman and child outcomes (43). Our finding of high comorbidity between perinatal PTSD, depressive symptoms, and IPV highlights the need for studies to measure a range of CMDs and aetiologically relevant social determinants. Further research into perinatal PTSD and trauma symptoms, especially their association with birth and other obstetric trauma. Such studies in representative community samples will aid the development of trauma-informed, context-appropriate interventions for women across the perinatal period.

Strengths and Limitations

This is the first study in Ethiopia and one of few from LMICs, to investigate the relationships between trauma symptoms, IPV, obstetric complications and ANC satisfaction using validated measures in a large sample. Limitations include potential under detection of traumatic events, PTSD and IPV despite use of validated measures and highlights need for further studies how trauma symptoms may manifest differently in this setting and development of targeted interventions to elicit sensitive disclosure. ANC satisfaction may have been impacted by response bias; attention is needed to confidential ways of providing women with safe spaces to candidly disclose their experiences. The low recording of obstetric complications, inconsistent with national prevalence estimates, highlights how health system strengthening initiatives need to address the quality of data recording by clinicians. Future research should explore maternal health care workers' and other relevant stakeholders', including intimate partners' perspectives on high quality ANC and person-centred care.

Conclusions

Pregnant women attending ANC in Ethiopia report frequent exposure to traumatic life events, particularly physical violence. However, the prevalence of detected probable PTSD is low. IPV is associated with perinatal PTSD symptoms. Obstetric complications and IPV were under-reported, relative to previous studies in Ethiopia. ANC satisfaction was lower in women with probable PTSD. Our study highlights the importance of woman-centred approaches for improving recognition of trauma exposure, antenatal PTSD and the quality of ANC.

Funding acknowledgments

The research underpinning the findings presented in this paper was funded by the National Institute of Health and Care Research (NIHR) Global Health Research Unit on Health System Strengthening in

Sub-Saharan Africa (ASSET), King's College London (GHRU 16/136/54) using UK aid from the UK Government. CH and MP are funded by an NIHR global health research group on homelessness and mental health in Africa (HOPE; NIHR134325).
