Abstract: This Stage 1 Registered Report presents EchoCue™, an innovative tool designed to detect cortical visual impairments in uncooperative children aged 0 to 18, without requiring verbal instruction or active participation. The protocol delivers extreme-frequency auditory stimuli (very low and high), paired with directional visual flashes. Reflexive responses, such as eye blinks, gaze shifts, pupil dilation, and startle reactions, are recorded using an eye-tracking system and a flexible frontal EEG device. The assessment is entirely passive, standardised, and suitable for children who are otherwise difficult to evaluate using conventional methods.

Keywords: Cortical visual impairment, screening tool, reflex response, autism differential diagnosis, uncooperative children.

Introduction

Cortical Visual Impairment (CVI) is a major cause of childhood disability in Australia and high-income countries. There are many tools available for screening CVI, but none of them are suitable for uncooperative children (1). The difficulty is compounded by the fact that the origin of these disorders is not ocular but neurological, involving damage to the visual pathways or the cortex, which requires specific evaluation methods (2). Current tools for CVI rely on the child's ability to follow instructions or perform tasks, excluding many of the most affected children from standardised assessment (3).

This methodological impasse leads to a high risk of underdiagnosis and misdiagnosis. Indeed, there is significant symptomatic overlap between CVI and autism spectrum disorders (ASD), including peculiarities in eye contact, stereotypical behaviours, and atypical responses to sensory stimuli. This clinical overlap delays or even prevents the correct identification of visual impairments of cortical origin, thus depriving these children of appropriate and early care (4). There is therefore an urgent clinical and scientific need for an evaluation methodology capable of passively testing children's perceptual abilities (5). Such an approach must be able to dispense

with the active participation of the child in order to provide objective markers of the integrity of their neurosensory system.

It is in this context that EchoCue™ was conceived, a new methodological approach based on the integration of multimodal data such as visual (light, images), auditory (sounds, hertz frequencies, voices), vestibular (balance and movement), and proprioceptive (body position) for the screening of CVI. The protocol is based on the presentation of calibrated sensory stimuli (auditory and visual) and the synchronised capture of reflex responses (eye movements, blinks, startles) using an integrated eye tracking system and a motion sensor. While the primary goal of this protocol is to establish the method's initial validity, a recognised limitation is that future work on larger cohorts will be necessary to establish normative data.

Method

EchoCue™ is an original screening framework designed by Edwige Smague in 2025 as part of a doctoral research initiative. The device is not yet commercialised and is currently under academic development for validation in Australia. The methodology presented in this article is based on the EchoCue™ conceptual framework, which enables the passive screening of neurovisual functions using strategically calibrated multimodal sensory stimuli. This section outlines the theoretical foundations of

the approach, the standardised experimental protocol, the technological setup required, and the data quantification process.

Table 1. Hypotheses, Variables, Planned Analyses, and Success Criteria for Stage 1 Registered Report

Key hypothesis	Hypothesis	Key variables	Planned statistical analysis	Success criterion
H1a Confirmatory	The CVI group will exhibit significantly longer saccadic reaction times (SRT) compared to the ASD and Typically Developing (TD) groups.	**Independent Variable (IV):** Group (CVI, ASD, TD) **Dependent Variable (DV):** SRT (in ms)	A linear mixed-effects model (LMM) will be fitted to analyse SRT data, with Group as a fixed effect and Participant ID as a random effect.	A statistically significant main effect of Group on SRT ($p < .025$).
H1b Exploratory	CVI and ASD groups will exhibit different patterns of startle reflex modulation by audiovisual stimuli, compared to the TD group.	**IV**: Group, Stimulus Condition **DV**: Startle Amplitude	A linear mixed-effects model (LMM) will be used to analyse startle amplitude, testing for a Group × Condition interaction.	A statistically significant Group × Condition interaction effect ($p < .025$).
H2a Confirmatory screening accuracy test	The objective metrics measured will be able to reliably classify participants as CVI vs. non-CVI.	**Predictors**: SRT, Startle Amplitude. **Outcome**: Group Status (CVI / non-CVI)	Receiver Operating Characteristic (ROC) curve analysis will be conducted.	An Area Under the Curve (AUC) value greater than 0.75.

Note. AUC: Area Under the Curve; DV: Dependent Variable; H: Hypothesis; IV: Independent Variable; LMM: Linear Mixed-Effects Model; p: p-value; ROC: Receiver Operating Characteristic; SRT: Saccadic Reaction Time; TD: Typically Developing.

Sample Size Justification: The planned sample size (n=15/group) is based on recruitment feasibility for this initial proof-of-concept study. Smallest Effect Size of Interest (SESOI): The primary confirmatory

test (H1a) is conceptualised to detect a large effect size (Cohen's $d \geq 0.8$), as a clinically useful screening tool must be sensitive to clear, robust differences in neurosensory function. Data from this study will provide effect size estimates to power future, larger-scale validation trials designed to meet stricter statistical thresholds (e.g., 90% power).

Participants

A total of 45 participants will be recruited, divided into three age- and sex-matched groups (n=15 per group): (1) children diagnosed with CVI; (2) a clinical control group with a diagnosis of ASD and no known visual impairment; and (3) a typically developing control group.

Power analysis and sample size justification

Given the novelty of the EchoCue™ method, no prior data is available to conduct a precise a priori power analysis. Therefore, the sample size for this initial proof-of-concept study is justified based on two principles: feasibility and the detection of a clinically meaningful effect size as informed by the existing literature.

To align with the high standards of top-tier journals such as Cortex, our ultimate goal is to power studies to detect a large effect size (Cohen's $d \geq 0.8$). This threshold was chosen because a clinically useful screening tool, such as the one proposed, must be sensitive to clear and robust differences in neurosensory function rather than subtle statistical variations. An effect of this magnitude would represent a readily observable impairment, providing a strong and unambiguous signal for clinicians.

A formal power calculation based on these parameters indicates that a sample of 33 participants per group would be required to achieve 90% power at a strict alpha level of .025. The currently planned target of 15 participants per group is based on recruitment feasibility for this initial study. I acknowledge this sample provides approximately 80% power at a standard alpha of .05. The primary goal of this first stage is therefore to establish the viability of the protocol, refine the methodology, and generate robust effect size estimates from the data. These estimates will be used to power future, larger-scale validation trials designed to meet the stricter 90% power threshold required for confirmatory research.

Recruitment and inclusion/exclusion criteria

Participants will be recruited from key paediatric institutions and support networks in Brisbane, Australia, including the Queensland Children's Hospital (QCH), Mater Children's Private Brisbane, National Disability Insurance Scheme (NDIS), Vision Australia, Autism Cooperative Research Centre (Autism CRC), CVI Australia, Statewide Vision Impairment Services (via the Department of Education Queensland), Queensland University of Technology (QUT), and The University of Queensland (UQ). Inclusion criteria for the CVI group will be: (1) a formal clinical diagnosis of CVI from a qualified professional (e.g., paediatric

neurologist or ophthalmologist); (2) evidence that the visual impairment is of neurological origin and not primarily explained by a significant ocular pathology; and (3) an age between 0 and 18 years.

Exclusion criteria for all groups will be: (1) the presence of a severe, uncorrected ocular pathology that could primarily account for visual deficits; (2) a diagnosed severe or profound hearing impairment that would prevent perception of the auditory stimuli; or (3) an unstable medical condition precluding participation in a 15-minute session. Written informed consent will be obtained from the parents or legal guardians of all participants.

Theoretical basis: the link between audition and vision in CVI screening

The EchoCue™ protocol is based on a passive assessment method that tests the child's neurosensory functions without the need for the child to understand instructions or actively participate(7). The approach involves exposing the child to a series of finely calibrated auditory and visual stimuli while synchronously recording their involuntary reflex responses (8)(such as blinks, micro-saccades, or startles) and visual orientation responses. A key element of this method is using a wide range of sound frequencies, from 20 to 8000 Hz. Each frequency range allows distinct neurological

circuits, both subcortical and cortical, to be explored in order to better understand how the brain perceives, integrates, and responds to multisensory stimuli,(9).

Low-frequency sounds (20—250 Hz) act as a subcortical marker. This range is particularly important for uncooperative children (10). These frequencies are perceived by the human body as both vibrotactile stimulation and sound (11). They are transmitted partly by bone conduction, directly stimulating the cochlea and vestibular system, thus bypassing any disorders of the outer or middle ear (12). More important still, they are processed primarily by the archaic neural circuits of the brainstem due to their simple acoustic configuration and their strong ability to arouse sensory alert systems (13) (14). They are particularly effective at triggering involuntary reflexes managed by the brainstem, such as the stapedius reflex (an involuntary auditory reflex that protects the inner ear from loud sounds) and the startle reflex (15, 16). The use of these frequencies thus makes it possible to measure a basic neurological response, a sign of the integrity of the subcortical pathways, even before the information reaches the higher cortical areas (17).

Medium to high frequencies (250—8000 Hz) are used for cortical analysis. This range is essential for assessing the classical auditory pathway and higher cognitive functions (18) (19). It is necessary

for multisensory integration tasks, where the brain has to compare and merge auditory information with visual information (20). Difficulty processing these sounds or integrating them correctly with a visual stimulus may reveal dysfunction in associative cortical areas (e.g., the temporoparietal junction), which are often involved in CVI (21).

The use of an audio method for screening CVI is based on the brain's multisensory integration function (8) (22). Since CVI is a brain disorder that affects visual processing and not an eye condition, we can use a powerful auditory stimulus to establish a reliable baseline response. The way a simultaneous visual stimulus alters, or fails to alter, this baseline response can be used to objectively quantify the brain's capacity to process visual information (23). This is an indirect method of testing brain visual function without ever asking the child, "Did you see that?"

The standardised screening protocol

The test session is brief, lasting between 12 and 15 minutes. It is structured in five sequential blocks, each targeting a distinct aspect of sensory or neurological processing (24). The specific pure tones used in the protocol (e.g., 125 Hz, 500 Hz, 2000 Hz) are aligned with standard audiometric test frequencies, ensuring compatibility with established clinical practices (25) (26).

Table 2. Structured sequence of the EchoCue™ multisensory screening protocol

Block	Stimulation method	Frequencies / Modalities	Parameters	Clinical goal	Key markers to measure
1.	Auditory-only condition	125 Hz (infrabasse), 500 Hz (grave), 2000 Hz (médium), 8000 Hz	Directional sounds (L/R)	Explore subcortical (low-frequency) and cortical (high-frequency) auditory pathways, detect startle reflexes and lateralised orientation	Startle reflex, micro eye movements, orientation response towards sound
2.	Visual-only condition	LED flash (40 ms)	Unilateral hemifield L/R Without sound	Assess the primary visual pathway and visual attentional orientation	Pupillary reflex, head or eye movement towards the flash
3.	Congruent audiovisual stimuli (audio and visual cues aligned in spatial direction)	Synchronized sound and flash 500 Hz and 2000 Hz	In the same hemifield (e.g., L + L)	Measure harmonious multisensory integration (aligned and congruent)	Enhanced reflex response, rapid and smooth orientation
4.	Incongruent audiovisual stimuli (audio and visual cues presented in conflicting directions)	Sound and flash 1000 Hz to 3000 Hz	Presented in opposite hemifields (e.g., L + R), Sound (L) vs Flash (R) and vice versa	Evaluate sensory processing capacity under cross-modal conflict	Increased reaction time, hesitation or absence of response
5.	naturalistic stimulu	Familiar voices, animal sounds 250-4000 Hz synchronized with animated images	Familiar voices, animal sounds, synchronised with an animated image	Probe social attention and semantic recognition. Simulate ecological situations to capture spontaneous attention	Prolonged fixation, smiling, vocalisation, motor imitation

Note. L/R = left/right hemifield; Hz = Hertz. Each block presents a specific sensory configuration to evaluate reflexive and orienting responses across auditory, visual, and multisensory conditions. Block 5 introduces ecologically valid stimuli to assess spontaneous social and semantic attention.

The EchoCue™ protocol is structured as a progressive sequence of assessments, beginning with unimodal conditions to establish baseline responses and progressing towards increasingly complex multisensory integrations. Blocks 1 and 2 independently assess the integrity of subcortical and cortical auditory and visual pathways, establishing reference markers for reflexive and orienting responses (17). The use of frequencies such as 125 Hz, 500 Hz, and 2000 Hz aligns with standard clinical audiometric testing (27) (28). Block 3 evaluates the capacity for harmonious multisensory integration through spatially congruent audiovisual stimuli, a hallmark of intact sensory convergence (20). In contrast, Block 4 introduces spatial incongruence between auditory and visual inputs to probe the child's ability to resolve cross-modal conflict, a process often impaired in neurodevelopmental disorders (29). Block 1, in particular, leverages low-frequency tones that can stimulate vestibular and cochlear structures via bone conduction and trigger reflexes such as the auditory startle response (30) (31). Finally, Block 5 incorporates ecologically valid, semantically rich stimuli (e.g., familiar voices and animals) to assess social attention and semantic processing, thereby maintaining engagement while enabling the detection of higher-order cognitive markers. This design ensures the protocol’s clinical relevance, even in children without verbal or behavioural responsiveness.

System architecture and data acquisition

The implementation of this protocol requires a simple, accessible, and non-invasive technological platform capable of fulfilling three essential functions:

- **Stimulus Generation:** A central unit, such as an iPad Pro-type digital tablet, generates the protocol's audio-visual stimuli with precise temporal synchronisation (32).
- **Eye-Tracking:** The tablet's integrated infrared camera captures gaze dynamics (saccades, blinks, pupillary reflex) through software APIs (e.g., ARKit). This method removes the necessity for costly external hardware (33).
- **Motion detection:** A single, external wireless sensor is necessary to quantify the fine motor responses that the tablet cannot measure. A millimetre-wave (mmWave) radar is used to accurately detect micro-movements, startle reflexes, and variations in respiratory rate from a distance of at least 60 cm (34).
- **Neural activity monitoring (optional):** A flexible, front-mounted EEG headband may be integrated to record low-density electrophysiological signals. This setup enables the detection of auditory and visual evoked potentials (e.g., MMN, P300), providing an additional objective layer of cortical response data (35, 36) (37).

The most critical function of the system is to ensure the perfect synchronisation of all data streams (stimuli, ocular data, motion data) on a single timeline (38).

Data quantification and analysis

In line with the system's philosophy, the EchoCue™ software does not provide an interpretation or diagnosis. Its role is to act as a quantification engine that applies signal processing algorithms to transform raw data into objective metrics. These metrics are then presented factually to the clinician (39).

The main calculated metrics are:

- The average saccadic reaction time (in ms) (40).
- The success rate of visual target tracking (41) (42).
- The amplitude of the startle reflex (as measured by radar) (43).
- The average respiratory rate and its variations during the blocks (44).
- The percentage of sensory dominance (visual vs. auditory) during conflicting trials (45).

To ensure technical rigour, metrics are defined operationally. For instance, the startle reflex is identified as a sharp increase in motion energy exceeding a predefined threshold within 200 ms of the stimulus (43), distinguishing it from slower, ambient movements. Sensory dominance is calculated as the percentage of trials in the conflicting block where the initial saccade was directed

towards the auditory versus the visual stimulus (45). These quantified data are compiled into a clinical report, allowing the practitioner to base their evaluation on objective and reproducible evidence (40).

Data-based exclusion criteria

Pre-specified criteria will be applied to ensure data quality.

- Trial-level exclusion: Individual trials will be excluded from analysis if eye-tracking data quality is poor (e.g., the tracker loses the pupil for more than 50% of the trial duration).
- Participant-level participation: A participant's entire dataset will be excluded if fewer than 60% of their trials are deemed valid after trial-level cleaning, or in the event of a significant equipment malfunction.

Statistical plan

To test for group differences in performance, a mixed-effects model will be used with Group (CVI, ASD, Control) as a between-subjects factor and Stimulus Location (Left, Right) as a within-subjects factor. The dependent variables will be Saccadic Reaction Time (SRT), pupil response magnitude, and startle reflex amplitude.

Diagnostic accuracy

Receiver Operating Characteristic (ROC) analysis will be used to determine the ability of our measured variables to classify

participants correctly into the CVI vs. non-CVI groups. The Area Under the Curve (AUC) will be the primary metric.

Criteria for success

This validation study will be considered successful if the following criteria are met: (1) The group difference in the primary dependent variable (SRT) is statistically significant ($p < .025$), and (2) the AUC for the ROC analysis is greater than 0.75, indicating good to excellent diagnostic accuracy.

Declarations

Ethics Statement: This research protocol has been developed in preparation for a future doctoral project. Formal ethics approval will be sought from the responsible Human Research Ethics Committee (HREC) at the author's host institution prior to the commencement of any research activities involving human participants.

Data and materials availability

In accordance with TOP guidelines, all processed anonymised data, analysis scripts, and digital study materials required to reproduce the study's findings will be made publicly available on a repository such as the Open Science Framework (OSF). The EchoCue™ software script developed for stimulus delivery in this non-

commercial, academic research project will be included in this public deposition.
