Abstract

Background: Diabetic peripheral neuropathy (DPN) affects approximately 50% of individuals with diabetes and is a risk factor for amputations. Unfortunately, foot exams and screening tools are inconsistent and miss early-stage nerve damage. A smartphone-based application that delivers controlled vibrations, records patient responses, and computes a vibration perception threshold (SVPT) may present an accessible, precise monitoring avenue. This study assesses the clinical relevance and precision of SVPTs as a nerve health metric in patients with diabetes.

Methods: We measured SVPTs in 71 patients with pre-diabetes or diabetes and compared their efficacy with tuning fork exams. We analyzed the correlation between SVPT and Rydel-Seiffer tuning fork (RSTF) scores, along with their relationship with clinical DPN markers such as hemoglobin A1c (HbA1c), age, and disease duration using multivariable linear regression.

Results: SVPTs moderately correlated with RSTF scores ($R_s = -0.43$, $p = 0.0019$). Among adults aged 50 to 69, SVPTs correlated significantly with clinical markers ($F(4, 29) = 4.76$, $p = 0.00447$, *Multiple* $R^2 = 0.396$, *Adjusted* $R^2 = 0.313$, $\epsilon = 0.167$). The interaction between age and HbA1c was positively associated with SVPTs ($\beta = 0.118$, $p = 0.001$), while SVPTs were negatively associated with diabetes duration ($\beta = -0.098$, $p = 0.003$).

Conclusions: We present a clinically relevant, patient-operated smartphone application for DPN monitoring, tested on patients with varying DPN risk. This novel platform has the potential to provide a precise, reliable, and accessible avenue for identifying individuals at risk of developing DPN complications, prior to overt clinical manifestation.

Introduction

Diabetic peripheral neuropathy (DPN) affects approximately 50% of individuals with diabetes, resulting in pain, infections, ulcerations, amputations, sleep disturbances, reduced daily function, and higher medical costs [1, 2, 3]. While various tools exist for DPN screening and monitoring, the lack of high-resolution, accessible, fast, inexpensive, and standardized methods has led to under-diagnosis of DPN, resulting in unnecessary medical burdens [2, 4].

Common DPN screening methods such as monofilament and tuning fork exams are fast, inexpensive, and easy to perform, but have limited resolution and fail to detect early-stage, large-fiber, nerve damage [1, 5, 6]. Furthermore, the increasing occurrence of virtual visits leads to the exclusion of many physical exams such as monofilament and tuning fork exams [7]. Studies indicate that foot screening is only done in about 50% of individuals with diabetes [8]. More precise exams, like nerve conduction studies, are inaccessible to many due to their expensive cost and the amount of time required to conduct the exams [9]. Hence, a precise, accurate, accessible tool that monitors changes in peripheral nerve health over time could revolutionize approaches to patient care.

Recent research suggests that smartphones have the potential to measure DPN-related vibration perception thresholds (VPTs). Smartphone vibration apps have been found to discriminate between healthy patients and patients with severe DPN [10, 11]. In 2023, Torres et al. characterized

smartphone vibrations and found that smartphone-based VPTs (SVPTs) correlate with monofilament thresholds on the index fingers of patients without diabetes [12]. In 2024, Adenekan et al. reliably measured SVPTs in age-diverse, healthy adults, at multiple body sites, and correlated the SVPTs with tuning fork-based VPTs [13, 14]. Also in 2024, Piaggio et al. developed a DPN exam using a smartphone with 3D-printed accessories [15]. Specifically, the accessories included a spherical tip that transmits vibrations between the smartphone and the body part of interest during the vibration testing and including two-point discriminators with different discriminator distances, used during the two-point discrimination portion of the sensory testing. Most recently, Owen et al. measured SVPTs in the index finger of neurologically healthy volunteers and correlated their results to monofilaments, tuning forks, and nerve conduction studies [16].

While these studies move toward developing an effective VPT-based DPN screening method, none of these studies provide a platform that is housed entirely in a smartphone (no separate device needed), operated independently (without an experimenter or clinician), fast (< 2 minutes), robust, based on validated, quantitative psychophysical methods, and performs well for patients with diabetes, who do not yet have severe DPN. Existing studies also lack analysis of how SVPTs correlate with clinical features of DPN progression like blood glucose control, age, and disease duration. Therefore, in this work we assess how SVPTs correlate with clinical markers of DPN in people with varying risk and demonstrate that SVPTs could potentially be used for early

identification and monitoring of those patients.

Methods

Study Design

This was a cross-sectional study to evaluate a novel SVPT tool with traditional methods for DPN assessment (RSTF exam and monofilament exam). This study was approved by the Stanford University Institutional Review Board (Protocol 63873). All participants provided written informed consent.

Eligibility Criteria

Individuals aged 18 years and older and diagnosed with pre-diabetes or type-2 diabetes were recruited primarily via visits to the Stanford Endocrinology Clinic or by phone (with their treating physician's permission). A few participants were recruited through Stanford pre-diabetes nutrition classes, campus and online flyers, and Stanford's World Diabetes Day Fair.

We excluded patients with known touch perception deficits identified through standard monofilament exams conducted by their clinicians, as these patients already have severe sensory impairments. Our goal was to determine whether our tool could monitor early changes in large-fiber nerve health.

Study Procedure and Data Collection

Participants completed a single one-hour session consisting of a low-frequency and high-frequency SVPT exam, a RSTF exam, and a monofilament exam. Exam ordering was randomized. All measurements were

collected on the participant's dominant foot.

Medical History

Prior to completing the study, participants completed a pre-survey that inquired about demographic information, diabetes duration, presence of common neuropathy symptoms (i.e. pain, numbness, and tingling), and foot dominance (the foot one would use to kick a ball). Participants also completed the questionnaire portion of the Michigan Neuropathy Screening Instrument (MNSI [17]) to identify DPN symptoms. Anthropomorphic measures and laboratory measurements (i.e. body mass index and HbA1c) were assessed from electronic health records (EHR).

Touch Sensitivity Measurement Methods

Figure 1 provides an overview of the setup for the SVPT exams. We used an iPhone app that modulates smartphone vibrations to stimulate a user's foot at different intensity levels. Through this app, users respond to vibrations and the app calculates their vibration perception threshold, a recognized indicator of nerve health [13, 14]. Specifically, this app consisted of a low and high-frequency SVPT exam on an iPhone 14 Pro Max. During the low-frequency SVPT exam, vibration frequency was held constant at 80 Hz (*hapticSharpness* = 0, Apple Core Haptics Parameter), while the amplitude (*hapticIntensity*, Apple Core Haptics Parameter), was autonomously modulated using the staircase method ([13, 14]) and visualized in Figure 1C. This method was also used for the high-frequency exam except that the phone vibrations were held constant at 230 Hz (*hapticSharpness* = 1). These

two frequencies stimulate the Meissner and Pacinian corpuscles, which are largely responsible for our ability to feel vibrations and are both impaired by DPN progression [18, 19, 20, 21]. Participants completed a 2-minute sample trial to familiarize themselves with the test before the measurement trials (2 minutes each). Three measurement trials were completed for each condition (high and low frequency). Mean SVPTs for each condition are presented in the results. Participants who had SVPTs above the phone's maximum vibration output (*hapticIntensity* = 1) are recorded as *over*, since their threshold cannot be measured with the platform. Participants wore noise-canceling headphones playing white noise to eliminate noise confounds (Figure 1A).

We used standard protocols for the 10g monofilament (Baseline Evaluation Instruments) and the 64 Hz RSTF (US Neurologicals) exams [22]. Similar to the SVPT, participants completed a sample trial and then the RSTF score was measured three times. The mean RSTF scores were analyzed.

To understand the relationship between SVPT and standard VPT exams, we calculated correlation coefficients between the low-frequency SVPT and RSTF score. As a baseline, we compared the RSTF score to low-frequency SVPTs rather than high-frequency SVPTs because the RSTF's frequency of 64 Hz is closer to the low-frequency SVPT's 80 Hz, while the high-frequency SVPT operates at 230 Hz.

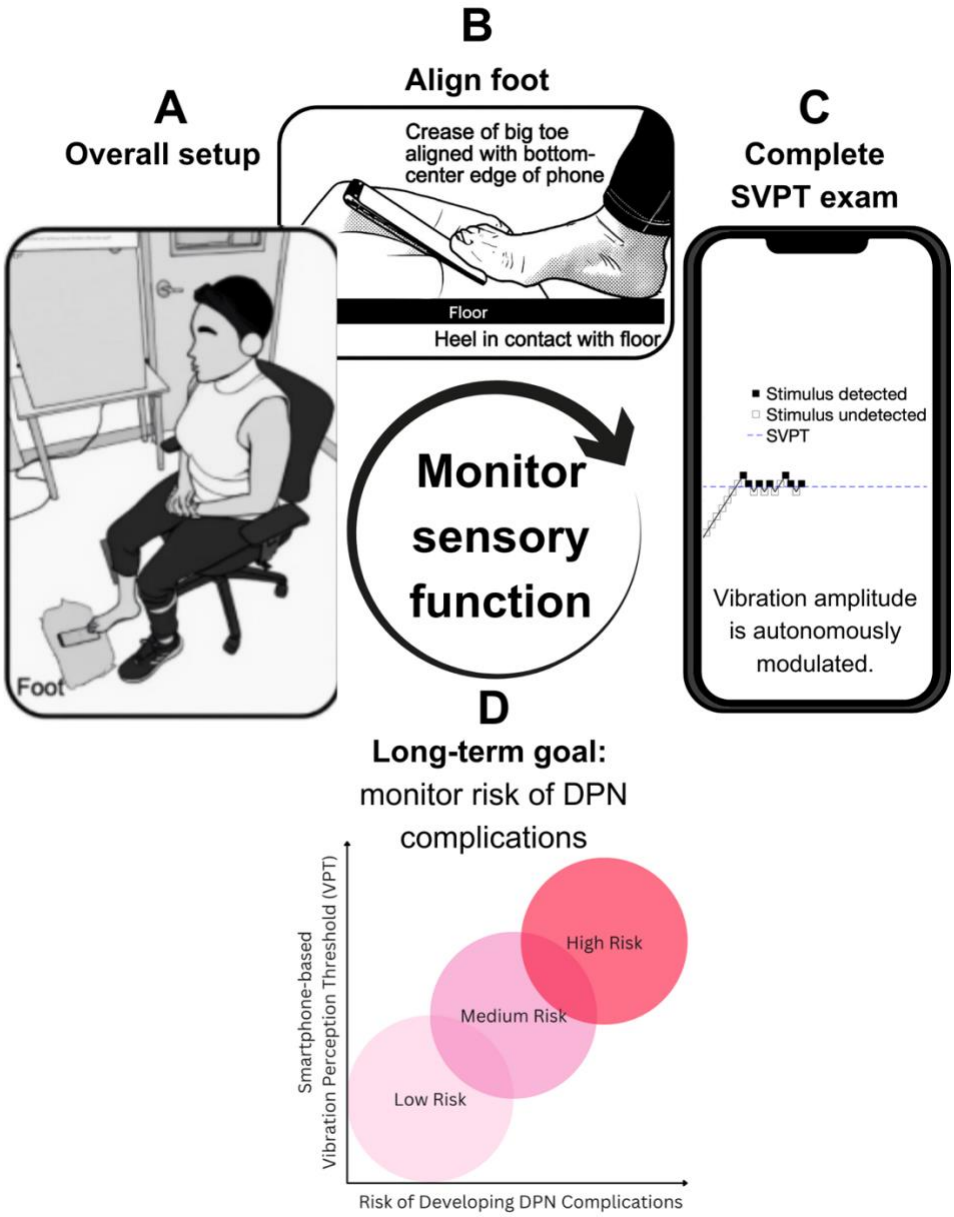

Figure 1: Smartphone-based vibration perception threshold (SVPT) setup and overview. (A-B) Users can complete the SVPT exam independently by placing their foot on the phone. (C) The phone then autonomously modulates the amplitude of various vibration stimuli at a given stimulation frequency. When users provide a verbal cue that they detected the vibration, the vibration amplitude is decreased. Otherwise, the vibration amplitude is increased. Upon

reaching 8 reversals, the SVPT is calculated. (D) Our long-term goal is to provide an accessible platform for monitoring the risk of developing diabetic peripheral neuropathy (DPN) complications. Note: Panels (A) and (B) are adapted from Adenekan et al. 2024 [14] © IEEE 2024. Panel (C) is adapted from Adenekan et al. 2024 [13] © IEEE 2024.

Statistical Analysis

Statistical Model Development

We constructed a multivariable linear model with SVPT (output) and clinical features that are associated with DPN incidence (inputs). We expected that cumulative blood glucose levels (HbA1c), diabetes duration, and age would correlate with DPN incidence based on previous research [2, 23, 24, 25]. This is our first-order model:

$$\text{SVPT} = \beta_0+\beta_1*Age+\beta_2*HbA1c+\beta_3*(Age*HbA1c)+\beta_4*(DiabetesDuration)+\epsilon \quad (1)$$

where β_0 is the intercept, β_1, β_2, β_3, and β_4 are regression coefficients, and ϵ is the residual standard error. Coefficients were found via dataset fitting. This linear model allows us to preserve interpretability to validate our platform. Complex models like random forest approaches or neural nets would be prone to overfitting and lack interpretability. To account for the cumulative nature of DPN progression, we used average HbA1c measurements (over five years) in our model (see Supplemental Information).

Initial data processing for SVPTs was conducted in Matlab (Version 2022b)

and statistical analyses were performed using R (Version 4.3.1).

Model Evaluation

We evaluated our model by measuring variance in SVPT data captured by the selected features (via *Adjusted* R^2). Features with statistically significant impacts on SVPT were identified using model coefficients and p-values ($p < 0.05$). We investigated the model's limitations by conducting residual analyses using R (Version 4.3.1) as presented in the Supplemental Information.

Results

Participant Demographics

Seventy-one adult participants with a known history of type 2 diabetes or pre-diabetes completed this study. Three participants were excluded due to their inability to complete the protocol ($n = 1$), false positives ($n = 1$), and severely ulcerated feet ($n = 1$). As shown in Table 1, the majority of our population had type 2 diabetes, with most having an HbA1c of less than 8%. Approximately two-thirds of the participants were women.

Table 1: Participant Demographics and Medical History, N = 68*

Disease State	Pre-diabetes	9 (13.2%)
	Type 2 diabetes	59 (86.8%)
Age [*yrs*]	18 to 49	9 (13.2%)
	50 to 59	16 (23.5%)
	60 to 69	31 (45.6%)
	70+	12 (17.6%)
	Pre-diabetes: Mean (Range)	62.6 (43,82)
	Type 2 diabetes: Mean (Range)	61.6 (38,78)
Sex assigned at birth	Male	24 (35.3%)
	Female	44 (64.7%)
Race/Ethnicity	Native Hawaiian / Pacific Islander	1 (1.5%)
	Black / of African Descent	2 (2.9%)
	Hispanic / Latino	9 (13.2%)
	Asian	26 (38.2%)
	White	30 (44.1%)
	Other (Israelite)	1 (1.5%)
	Other (Middle Eastern)	1 (1.5%)
	Other (Portuguese)	1 (1.5%)
	Other (West Indian/ Caribbean)	1 (1.5%)
	Other (Indian)	2 (2.9%)
Symptoms: Foot pain, numbness, or tingling	Self-reported "Yes"	29 (43%)
HbA1c (5 yr. average) [%]	Pre-diabetes: Mean ± std	5.9± 0.4
	Type 2 diabetes: Mean ± std	7.1± 0.9
	Type 2 diabetes: HbA1c less than 7%	32 (47.5%)
	Type 2 diabetes: HbA1c less than 8%	54 (79.7%)
Time Since Diagnosis [*yrs*]	Pre-diabetes: Mean± std	5.1± 2.8
	Type 2 diabetes: Mean ± std	13.7± 7.7
BMI [kg/m^2]	Mean ± std	29.6±7.3
Footedness	Right	60 (88.2%)
	Left	3 (4.4%)
	Ambipedal	1 (1.5%)
	Unknown	4 (5.9%)

*Although we had 71 participants, only 68 were included in the final analysis. Three were removed due to inability to complete protocol, false positives, or severely ulcerated feet. Note that participants were allowed to select multiple race/ethnicity identifiers.

Smartphone-based Vibration Perception Threshold and Rydel-Seiffer Tuning Fork Correlations

There was a statistically significant, moderate negative Spearman's correlation ($R_s = -0.43$, $p = 1.9 \times 10^{-3}$) between the low-frequency SVPTs and RSTF scores (Fig. 2). We also found that: (1) Participants with RSTF scores lower than 3.5 (the abnormal cutoff for ages less than 85 years [26]) tend to have low-frequency SVPTs above 0.5, indicating that low-frequency SVPTs effectively identify individuals with impaired vibration perception as classified by the RSTF (left-shaded region); and (2) Participants with low-frequency SVPTs less than 0.5 tend to have RSTF scores above 4, which is considered normal for ages 41 to 60 [26], further indicating that low-frequency SVPTs can also identify individuals with normal vibration perception (right-shaded region).

Ceiling and Floor Effects of Age on Smartphone-based Vibration Perception Threshold

An important requirement for the SVPT platform is its ability to discriminate between normal, age-related VPT declines [27] and DPN-related impairments. Analyzing our study's age-diverse population, we observed that there is a

statistically significant, moderate, positive Spearman's correlation between low-frequency SVPT and age (Figure 3A, R_s = 0.31, p = 0.027) and high-frequency SVPT and age (Figure 3B, R_s = 0.28, p = 0.047). This moderate correlation is consistent with existing literature examining the effects of age on VPT using other devices [28]. We also observed that the SVPT platform may have limited utility for people younger than 50 as participants under 50 tended to have similar SVPTs (Figure 3). Similarly, the platform has limited utility for people older than 69 as these subjects tended to have SVPTs above the tool's maximum output vibration (Figure 3).

Similarly, we observed a statistically significant, moderate, negative Spearman's correlation between RSTF scores and age (Figure 4, R_s = −0.36, p = 0.002). We also observed that participants under 50 tended to have similar RSTF scores and that participants older than 75 tended to have RSTF scores that lie at the tool's minimum output vibration.

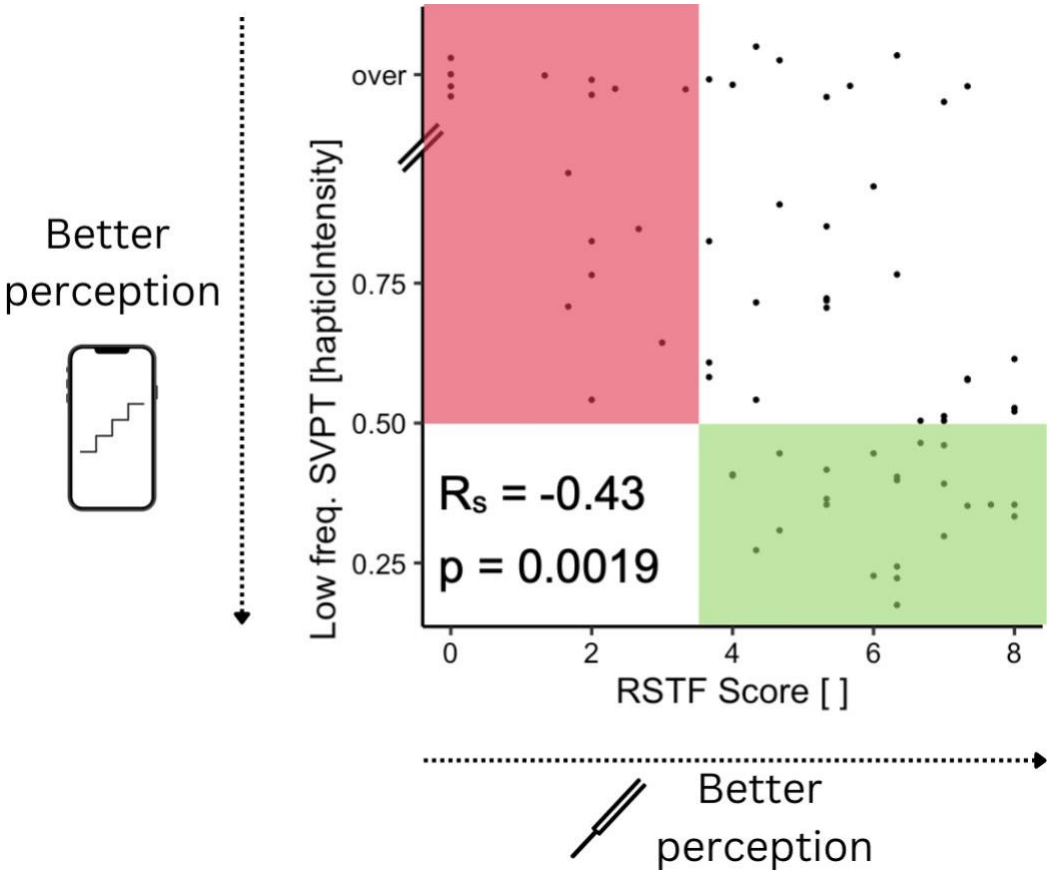

Figure 2: Correlations between smartphone-based vibration perception threshold (SVPT) and Rydel-Seiffer tuning fork (RSTF) score. The low-frequency SVPTs have a statistically significant, moderate correlation with the RSTF score. The smartphone-based tool can identify people with impaired vibration perception as measured on the RSTF (left-shaded region in red), and when the SVPT indicates that someone has good perception, that person also displays good perception as indicated by the RSTF score (right-shaded region in green). There is some discrepancy between the tools (detailed in the Discussion). Note: The *over* category is used for patients

who have SVPTs that lie above the phone's maximum vibration amplitude output.

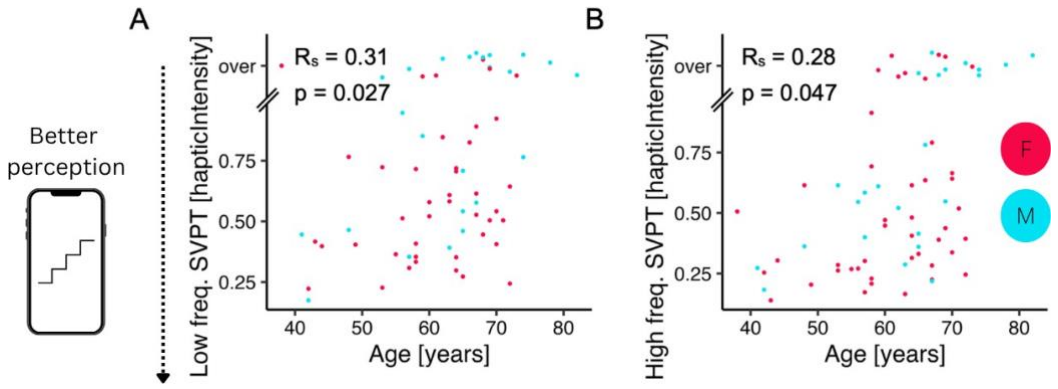

Figure 3: Correlations between smartphone-based vibration perception threshold (SVPT) and age. The SVPT has a statistically significant, moderate, positive correlation with age when the smartphone provides (A) low-frequency and (B) high-frequency vibrations. There are floor effects for users younger than age 50 and ceiling effects for users older than age 70. Note: The *over* category is used for patients who have SVPTs above the phone's maximum vibration amplitude output.

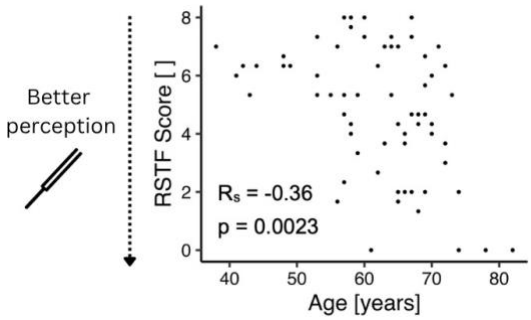

Figure 4: Correlations between the Rydel-Seiffer tuning fork (RSTF) score and age. There is a statistically significant, negative correlation between RSTF score and age. There are ceiling effects for patients younger than age 50 and floor effects for patients older than age 75.

Smartphone-based Vibration Perception Threshold Prediction from a Biologically-Relevant Model

To assess whether the smartphone-based platform could be used for early identification of those at risk of developing DPN complications, we constructed a multivariable regression model that predicts SVPTs from clinical features (Equation 1). Due to the previously identified floor and ceiling effects of age on SVPT, only participants who have diabetes and are aged 50 to 70 were included in the multivariable model. Our findings are below.

For low-frequency SVPTs, the model performs moderately well. The selected features explain approximately 31% of the variance in the low-frequency SVPTs (F (4, 29) = 4.76, p = 4.47×10^{-3}, *Multiple* R^2 = 0.396, *Adjusted* R^2 =

0.313, $\epsilon = 0.167$). There was also a significant effect of diabetes duration and interaction between age and HbA1c on the SVPTs (Table 2).

In contrast, a model with the same input features, but with an output of high-frequency SVPT (as opposed to low-frequency), does not explain the variance (F (4, 30) = 1.03, p = 0.409, *Multiple* R^2 = 0.121, *Adjusted* R^2 = 0.003, $\epsilon = 0.189$). A similar model using clinical markers to predict RSTF scores also did not fit the data (F (4, 29) = 1.89, p = 0.139, *Multiple* R^2 = 0.207, *Adjusted* R^2 = 0.0976, $\epsilon = 1.921$).

Table 2: Biologically-Relevant Multivariable Regression Model for the Smartphone-based Vibration Perception Threshold*

Feature	**Coefficient (β)**	**p-value**
Age	0.015	0.604
HbA1c	0.020	0.505
Interaction between Age and HbA1c	0.118	**0.001**
Time Since Diabetes Diagnosis	-0.098	**0.003**
(Intercept)	0.562	$< 2 \times 10^{-16}$

*Only participants who have diabetes and are between ages 50 and 70 yrs, are included in this multivariable regression model.

Discussion

Our main finding is that SVPTs provide increased precision and accuracy compared to RSTF scores and may have the potential to detect vibration perception deficits earlier than standard tools.

Smartphone-based Vibration Perception Threshold and Rydel-Seiffer Tuning Fork Correlations

Figure 2 shows that all participants with a low, low-frequency SVPT have a RSTF score that suggests better vibration perception (right-shaded region in green). This suggests SVPTs have high sensitivity for detecting unimpaired vibratory sense. Additionally, all participants with a RSTF score that suggests impaired vibration perception have a high, low-frequency SVPT (left-shaded region in red). However, there is some disagreement between the low-frequency SVPT and the RSTF score (right-unshaded region); a high RSTF score does not guarantee that an individual will have a low, low-frequency SVPT.

This discrepancy is likely because the RSTF and the SVPT platform have different stimulation patterns. The SVPT platform uses a dynamic staircase algorithm to calculate SVPT while the RSTF uses a constantly decaying stimulus. As a reminder, during the staircase algorithm, vibrations start small, increase until a person feels the vibration, decrease until they do not, increase again, and so on until there have been a set number of reversals (n = 8 for our current platform), at which point the SVPT is calculated by averaging the vibration amplitudes at each of the reversal points. In

essence, for each SVPT measurement, there are eight data points (reversals), while the RSTF has only one. During the RSTF exam, vibrations start with a high amplitude and decrease over approximately 20 seconds. As such, any delays in a participant indicating that they no longer feel the vibration would result in a higher RSTF score, corresponding to a recorded value that is better than the participant's true perception score. As such, the RSTF may be prone to overestimating someone's perception ability. This matches existing literature showing that fewer reversals result in threshold overestimates and larger variances [29]. Thus we are not concerned that the low-frequency SVPTs do not perfectly correlate with the RSTF scores, as the SVPT may present a more accurate measure. These results suggest that SVPTs might be able to detect vibration perception deficits earlier than RSTF scores.

Ceiling and Floor Effects of Age on Smartphone-based Vibration Perception Threshold

The results in Figures 3 and 4 show that participants younger than 50 had low, low-frequency SVPTs indicating better vibratory perception. DPN is a progressive condition that develops over time due to elevated blood glucose levels and other metabolic dysfunction [2]. Individuals under 50 may be more resilient to the effects of hyperglycemia than their older counterparts. Conversely, adults over age 69 experience a rapid age-related decline in vibration perception threshold (VPT) [27]. Thus it is not surprising that both the SVPT platform (Figure 3) and the RSTF (Figure 4) experienced

saturation in measuring VPT of people who are over age 69.

Smartphone-based Vibration Perception Threshold Prediction from a Biologically Relevant Model

The interaction between age and HbA1c had a coefficient of β_3 = 0.118 (p = 0.001). This suggests that younger adults maintain their SVPTs even with elevated blood glucose levels, but as patients age, elevated blood glucose levels are associated with higher SVPTs (impaired vibrotactile perception) as expected [30].

However, diabetes duration had a coefficient of β_4 = −0.098 (p = 0.003) which suggests that patients who have had diabetes longer have lower SVPTs (better vibrotactile perception) than those who have had diabetes for less time. This result is not what we expected; we hypothesized that patients who have had diabetes longer would have worsened perception, and thus higher SVPTs. This result might stem from our exclusion of patients with severe neuropathy (ulcerated feet or known inability to feel the 10g monofilament in the pad of the big toe) from the study. As such, patients with the worst DPN cases (who have likely had metabolic dysfunction for the longest periods) are not included in our study.

Additionally, most of the participants in our study were actively being treated for diabetes in the Stanford Endocrinology Clinic. Our unexpected result (higher diabetes duration corresponding to improved vibrotactile perception) could possibly be a function of health equity. It might be that these patients have had better access to endocrinology care for a longer

amount of time; this access to care could have resulted in better diabetes control and therefore improved SVPTs compared to those who have had care for less time. Given that many people are not aware that they have pre-diabetes [2, 31, 32], diabetes duration, recorded as self-reported time since diagnosis, does not exactly translate to time since initial sustained presentation of elevated blood glucose levels. Diabetes duration is more likely a measure of how long someone has had access to care than it is a measure of exactly how long someone has had elevated blood glucose levels. We do not have the dataset required to thoroughly assess this hypothesis.

Still, the model's moderate predictive power of low-frequency SVPT from clinical features suggests that SVPTs have the potential for eventual use in the early identification of those at risk of developing DPN complications. Unlike the low-frequency SVPTs, high-frequency SVPTs did not correlate with clinical markers of DPN incidence in this study. Current literature suggests that both Meissner (sensitive to low frequencies) and Pacininan corpuscles (sensitive to high frequencies) are affected by DPN, but because they may be differentially impaired [20, 21, 33], the low- and high-frequency SVPTs may yield different findings.

Limitations

While this study yielded promising insights, there are limitations. First, this study had a small sample size (n = 71) and was conducted at a single site. Nevertheless, our patients had HbA1c levels and symptoms that were representative of the broader population of Americans living with diabetes

([34] and Table 1). Another limitation is that SVPT primarily assesses large fiber nerve damage and cannot detect small fiber neuropathy. This limitation also applies to current screening methods including the monofilament and tuning fork exams, as well as the more precise, but invasive, electromyography-nerve conduction studies (EMG-NCS). Additionally, we did not compare the SVPT exam to the gold standard for quantifying large-fiber nerve damage, EMG-NCS, because most of our patients did not have an indication for EMG-NCS. Despite some limitations, this study sets the foundation for digital technology that could be used to identify and monitor people with diabetes independently (without using clinic time or staff), quickly (less than 2 minutes), and precisely (using a staircase algorithm to calculate VPT more comprehensively than VPT calculated using simple ramp-up algorithms via the RSTF).

Conclusions

We assessed the validity of a smartphone-based vibration perception threshold (SVPT) compared to traditional, clinical measures of DPN, in people with pre-diabetes and diabetes. We found that SVPTs moderately correlate with Rydel-Seiffer tuning fork-based vibration perception thresholds and that SVPTs of patients with diabetes aged 50 to 69 moderately correlate with indicators of DPN incidence (age, blood glucose control, and time since diagnosis).

To our knowledge, we present the first clinically relevant platform for DPN monitoring tested on patients with varying DPN risk that is fast, patient-

operated, and housed entirely within a smartphone. This platform has the potential to provide an accessible avenue for identifying individuals at risk of developing DPN complications, prior to overt clinical manifestation. Large, longitudinal, and prospective SVPT datasets paired with more sophisticated and inclusive models are needed to determine whether SVPT can effectively predict the severity of DPN and its associated complications in diverse populations.

Supplemental Information

HbA1c Measurements

To account for the cumulative nature of DPN progression, we used average HbA1c measurements (over five years) in our model. Over the five-year period, the median and interquartile range of the HbA1c entry count per patient were 10 and 8.25 respectively. Measurements over this period were typically available within the Stanford EHR of many patients; longer periods, such as 10 years, were not available for many patients. There has also been some recent literature suggesting that HbA1c variability, in addition to mean, is correlated with DPN progression [25]. We did not use HbA1c variability for this study because the data was sparse (many patients lacked regular readings for the entire 5-year period).

Regression Model Limitations

To assess the limitations of our multivariable regression model, we conducted residual analysis (Figure S1). From these figures, we observed that although the variance of the residuals is not perfectly consistent for all observations, there is no obvious pattern and thus no cause for concern (Figure S1A). From Figure S1B, we observed that there are no extreme outliers in our dataset (points that lie outside of Cook's distance), but there are some points that are close to having extreme influence (points near Cook's distance line). Lastly, the residuals of our regression model can be assumed to

be normally distributed as evidenced by the points in our Quantile-Quantile residuals plot falling roughly along a straight diagonal line (Figure S1C).

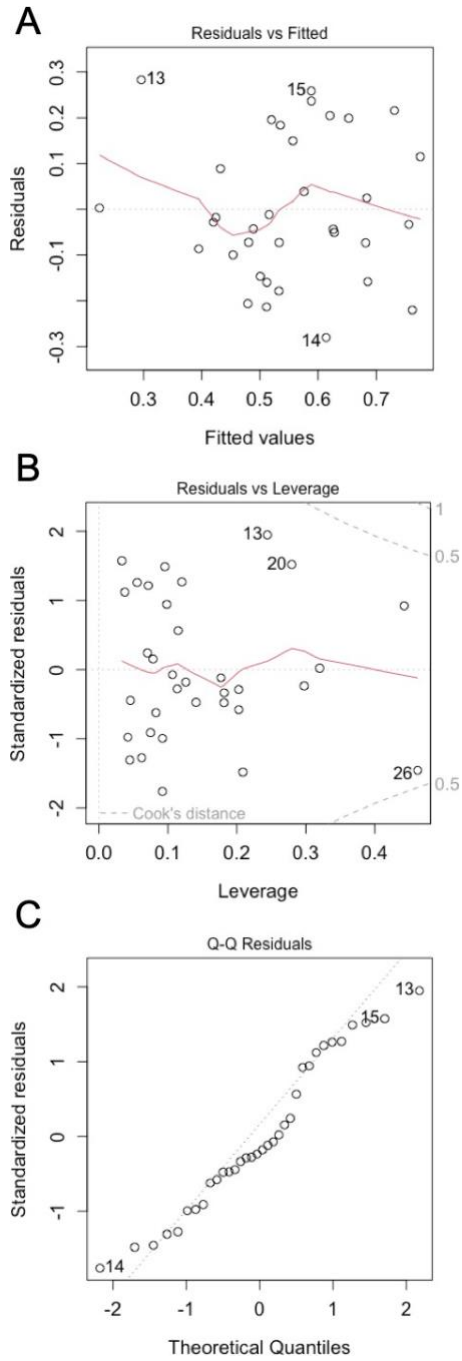

Figure S1: Residual analysis of the model. (A) Plot of the residuals vs. the fitted values. Although the variance of the residuals is not perfectly consistent for all observations, there is no obvious pattern and thus no cause for concern.

(B) Plot of the standardized residuals vs. the leverage. There are no extreme outliers in our dataset (points that lie outside of Cook's distance), but there are some points that are close to having extreme influence. (C) A Quantile-Quantile (Q-Q) plot of the standardized residuals vs. the theoretical quantiles. The points in this plot fall roughly along a straight diagonal line which suggests normally distributed residuals in the regression model.
