Abstract

Background: Sexual violence has been identified as one of the most serious forms of civilian victimisation in the Colombian armed conflict. Despite its importance, population-scale analysis of conflict-related sexual violence patterns has been limited, something essential for informing public health responses and prevention strategies.

Methods: We analysed two national databases of armed-conflict-related data from Colombia: the statutory Register of Victims (over 8 million registered individuals) and the National Centre for Historical Memory database of armed conflict events. We profiled victim demographics and used log-Gaussian Cox process modelling to identify geospatial clustering and Hawkes process modelling to test for temporal contagion. Analyses were conducted for data from the entire conflict period 1964-2024 and, more recently, 2014-2024.

Results: Victims were predominantly female (90.1-90.5%) and disproportionately from ethnic minorities. Sexual violence showed significant geographic clustering with a spatial range of 2.4km for the entire conflict period, reducing to 1.7km after controlling for population density. In 2014-2024, baseline intensity decreased but spatial clustering extended over a wider area (range = 2.5km unadjusted; 1.9km adjusted). Comparison of Hawkes process models revealed temporal contagion was largely driven by broader conflict dynamics. For the entire conflict, the unadjusted model indicated near-critical temporal dependency (branching ratio = 0.99) with multi-day temporal contagion (half-life = 3.7 days). The model adjusted for changes in background rates revealed little evidence for temporal contagion independent of changes in background rates. For 2014-2024, the unadjusted model similarly showed near-critical branching (branching ratio = 1.00) with extended decay (half-life = 10.04 days), whereas background rate-adjusted models indicated little evidence for temporal contagion beyond background rate changes.

Conclusions: Sexual violence in the Colombian armed conflict has shifted from concentrated, high-intensity incidents to more dispersed patterns increasingly shaped by structural and contextual influences rather than incident-specific characteristics.

Introduction

The Colombian armed conflict has endured for almost six decades and has disproportionally affected civilians with an estimated 18.3% of the entire population being affected by at least one form of violence (Unidad para las Víctimas, 2023). Sexual violence has been identified as one of the most serious types of civilian victimisation by the Colombian transitional justice process (Lopera & Concha, 2022) and victims of conflict related sexual violence are a recognised in law as a healthcare priority in terms of both medical treatment and psychosocial support (Paredes Mosquera et al., 2018).

Sexual violence is an urgent medical concern. Survivors of sexual violence are at increased risk for a range of acute and chronic medical conditions, including sexually transmitted infections, unintended pregnancies, traumatic injuries, and poor mental health (Ba & Bhopal, 2017; Stein et al., 2025). Sexual violence against civilians is endemic within armed conflict, manifesting in diverse forms and intensities across different contexts, countries, and phases of conflict (Cohen & Nordås, 2014). Consequently, understanding the dynamics of sexual violence in armed conflict is essential to public health approaches, informing prevention and treatment during conflict and in post-conflict periods (Bendavid et al., 2021).

Unfortunately, understanding armed-conflict-related sexual violence within Colombia has been difficult due to a paucity of studies that look at population data at a scale commensurate with the conflict itself, although some important earlier work has laid critical groundwork. Within the Colombian armed conflict, sexual violence has been noted to occur opportunistically (Wirtz et al., 2014), as part of broader gender-based violence endemic in society (Kreft, 2020), as well as being a systematic tool used by armed actors to achieve ‘strategic’ aims such as intimidation, demoralisation, retaliation, and territorial control (Blanco Blanco et al., 2021; Céspedes-Báez, 2010). A survey conducted by Urrego et al., (2020) found a 45.1% prevalence of sexual harassment, 16.8% prevalence of rape, and 3.9% prevalence of forced prostitution, although involved focused sampling of 1,975 women aged 15-44 in highly conflict-affected areas of Colombia, and restricted the sampling range to events occurring between 2010 and 2015. Partial statistics have been published as parts of reports identifying perpetrators or elaborating the impact of sexual violence (e.g. Observatorio de Memoria y Conflicto & Centro Nacional del Memoria Historica, 2021; San Pedro, 2010) with broad consensus that the armed conflict related sexual violence has uniquely and disproportionately affected women (Guzmán & Prieto, 2014), but there are a

lack of studies that have used population-level data to characterise sexual violence covering the duration of the conflict.

Public health approaches are best informed not only by an understanding of the demographic profile of affected individuals but also by data on how incidence spread geographically and evolve over time – something that is likely to be particularly important for understanding the spread of violence (Naumann et al., 2019). While existing studies have described prevalence and individual risk factors, understanding how sexual violence clusters and how these patterns evolve in relation to broader conflict dynamics would be useful for targeting post-violence support as well as understanding likely timescales for prevention.

Consequently, we used two population scale registers of armed conflict victimisation to understand the nature of sexual violence in the Colombian armed conflict: i) the national Register of Victims – a statutory register of over 8 million people who have been affected by the armed conflict where registration is a necessary step for qualifying for reparations; and, ii) the National Centre for Historical Memory database of Colombian armed conflict victimisations events – a register of armed conflict events based on multiple information sources that aims to record events nationally and over the entire duration of the conflict.

This study aimed to characterise the demographic profile of sexual violence victims and examine the spatial and temporal dynamics of conflict-related sexual violence in Colombia. We used log-Gaussian Cox process (LGCP) modelling to estimate the latent geospatial intensity of sexual violence events. Unlike simple prevalence maps, this approach accounts for spatial clustering, adjusts for population exposure, quantifies uncertainty, and can estimate risk in areas without events, providing a more robust estimation of high-risk areas for sexual violence. We also used Hawkes process modelling to test for temporal contagion, where the occurrence of one event may increase the risk of subsequent additional incidents. By comparing Hawkes process models with and without adjustment for baseline rate, we aimed to distinguish to the presence of short-term event-to-event contagion from slower-moving trends likely reflecting structural and contextual factors that drive sexual violence.

We focused on a time period covering the entire conflict duration (1964-2024) and the decade 2014-2024. This latter decade was chosen as it reflects more recent cases that are most likely to present to health and mental health services, as well as marking the Law 1719 in

Colombia, that established a framework for recognising, preventing, and providing reparations to victims of sexual violence and mandated medical, psychological, and legal support for victims.

Methods

The project received ethical approval from both the Ethics Committee of the Fundación Santa Fe de Bogotá in Colombia (ID CCEI-15951-2023) and the University College London Research Ethics Committee in the United Kingdom (Project ID: 8275/002).

Data sources

We used two data sources to profile victims of sexual violence in the Colombian armed conflict. We describe each of these data sources below.

National Register of Victims of the Colombian Armed Conflict

Known as the *Registro Unico de Víctimas* (RUV) in Spanish, this is an official registry of individuals affected by the armed conflict, where registration serves as a prerequisite for accessing state-provided reparations, and has existed since 1985. Enrolment in this registry occurs at designated offices, such as municipal authorities or the national Victims' Unit. As part of the registration process, individuals undergo an interview detailing the circumstances, and nature of the victimising events, and may be required to submit additional evidence. Under the legal framework, victims are defined as those who have experienced harm directly, or as immediate family members (including parents, children, or siblings) of those affected. Location is recorded in terms of municipality, the smallest administrative division of Colombia of which there are 1,104 in the country. Victims of sexual violence are eligible to register within a three-year period following the occurrence of the event. In 2024, legislation was passed acknowledging the unique barriers to reporting sexual violence, including a grace period extending until 2026 for victims whose prior registration attempts were denied solely due to the expiration of earlier statutory deadlines. This dataset was provided under agreement from the Colombian government and is not publicly available.

NCHM Database of Violent Events of the Internal Armed Conflict in Colombia

The National Centre for Historical Memory (*El Centro Nacional de Memoria Histórica* in Spanish) is a statutory institution in Colombia responsible for recording experiences of the victims of the armed conflict and was created as part of the country's transitional justice efforts. It maintains a database of violent victimisation that occurs as part of the armed conflict and gathers and cross-references data from several sources, including government records (e.g. legal rulings, military reports), non-governmental organisation reporting, truth commissions, testimonies from victims and communities, media reports, and academic studies. Events are timestamped and geolocated with latitude and longitude. The database is open licensed and publicly available online.

Exposure

Exposure to sexual violence is coded specifically in both databases and this was used as the exposure variable. For the Victims Register, sexual violence is defined in the Victims Unit assessment criteria (Unidad para las Víctimas, 2021, p. 3) as "Crimes against sexual freedom and integrity" and is defined as any act that violates the dignity, freedom or sexual integrity of a person through the use of physical, psychological or moral force that imposes a sexual behaviour against their will. The NCHM database does not itself have a specific definition of sexual violence, although the National Centre for Historical Memory define sexual violence as "Any act of a sexual nature imposed through the use of force, coercion, psychological oppression, abuse of power, or fear of violence" (Centro Nacional de Memoria Histórica, 2017).

Statistical analysis

For RUV data, analysis was completed using *R* version 4.5.0 (R Core Team, 2024) on a Windows secure analysis platform. For the NCHM data, analysis was conducted with *R* version 4.5.1 on a Linux x86 platform. Analysis code and output is available as Jupyter notebooks on the online archive: https://github.com/ElisavetPappa/col-conflict-sv

Summary statistics were calculated to describe the sample, identify the profile of victims and understand co-occurrence with other types of exposure to the armed conflict. We also used two approaches to identify geospatial and temporal clustering of sexual violence events for the entire armed conflict (1964-2024) and, more recently, 2014-2024.

Latent geospatial structure of conflict-related sexual violence

Due to the inclusion of timestamps and geographic coordinates for victimisation events, we used the NCHM Database to analyse the underlying geospatial structure of reported sexual violence incidents using a Log-Gaussian Cox Process (LGCP) model. LGCP models estimate spatial variation in event intensity by accounting for latent factors that influence risk patterns which are not directly observable in the data but detectable through spatial clustering beyond what would occur by random chance. Using the *inabru* (Bachl et al., 2019) and *stelfi* (Jones-Todd & van Helsdingen, 2024) packages, we implemented log-Gaussian Cox processes using integrated nested Laplace approximation for model fitting. Our analytical approach involved constructing a triangular mesh across Colombian territory and employing Gaussian Markov random fields to estimate the latent spatial intensity of sexual violence events. To account for population density, we rasterised back-projected census data (population divided by area) from the Colombian National Population and Housing Census available from the *ColOpenData* package (Otero et al., 2025) and extracted log-transformed values at mesh nodes. We compared this to a model that did not control for population density to assess the extent to which population density contributes to event clustering. The resulting intensity surfaces and latent fields were then projected to identify and visualise geographic clusters with elevated risk for sexual violence.

Temporal contagion of sexual violence events

To investigate whether sexual violence events increase the probability of further sexual violence, we used the NCHM Database and Hawkes process modelling to test for temporal contagion (also known as event dependence or self-excitation), where the occurrence of one event can elevate the risk of others occurring nearby in time. To prevent events recorded with the same time from artificially inflating contagion estimates, we added one day of random jitter to event times. Parameters were estimated via maximum likelihood using the *stelfi* package (Jones-Todd & van Helsdingen, 2024). The models estimated a baseline intensity (μ), an excitation parameter (α), and a decay rate (β). We also calculated branching ratio (α/β) to quantify the proportion of events expected to trigger additional events, reflecting the degree of event-dependence in the process (Hardiman & Bouchaud, 2014). A value approaching one indicates a near-critical, self-reinforcing system, in which each event is likely to lead to subsequent events. To understand to what extent temporal contagion was accounted for by changes in background rate, we compared the unadjusted model to a model

adjusted with a non-homogenous background rate function created by fitting splines to the incidence rate.

Results

Demographics of victims of sexual violence and differences between data sources

Demographics in terms of gender, ethnicity, and age of victims of sexual violence from each dataset are presented in Table 1.

	NCHM		*RUV*	
	N	*%*	*N*	*%*
Gender				
Female	15739	90.1%	30,505	90.5%
Male	1676	9.6%	2,674	7.9%
Other	-	-	533	1.6%
No information	62	0.36%	-	-
Ethnicity				
Afrocolombian	1,539	8.8%	6,858	20.3%
Indigenous	239	1.4%	1,105	3.3%
Palenquero	7	<0.01%	42	0.1%
Raizal	2	<0.01%	55	0.2%
Roma	1	<0.01%	19	0.1%
White / Mestizo	15,689	89.8%	25,636	76.0%
Age range				
Infancy (0-5)	149	0.9%	75	0.2%
Young childhood (6-11)	1018	5.8%	336	1.0%
Adolescence (12-17)	3896	22.3%	805	2.4%
Young adulthood (18-28)	5320	30.4%	4,551	13.5%
Adulthood (29-59)	4466	25.6%	25,407	75.4%
Older age (60+)	95	0.5%	2,529	7.5%
	Mean	*SD*	*Mean*	*SD*
Age	n/a	n/a	40.1	12.9

Table 1. Demographics of victims of sexual violence by source of information. CNMH = National Centre for Historical Memory Database; RUV = Register of Victims Database. Age only reported by age range in NCHM

As can be seen in Table 1, the RUV dataset has a greater proportion of ethnic minorities and a younger age profile of victims than in the NCHM dataset. Perpetrators of sexual violence in terms of armed group were only recorded in the NCHM dataset but this variable had very high rates of missing data meaning it is unlikely to provide reliable information: 17,405 cases

(99.59%) had no information in perpetrator, state agents were identified as perpetrators in 41 cases (0.23%), guerrilla groups in 26 cases (0.15%), paramilitary groups in 5 cases (0.03%).

Co-occurrence with other exposures to the armed conflict

There are very few instances of co-occurrence of sexual violence events with other armed conflict exposures events in the NCHM (Table 2). Registration of sexual violence victimisation co-occurs with registration of other armed conflict exposures at much higher levels in in the Victims Register (Table 3). This suggests that sexual violence tends to co-occur with armed conflict exposure events that are more personally directed in nature.

Armed conflict exposure event	*N*	*N Co-occurrence with sexual violence*
Witness to combat operations	51830	0
Massacres	27580	12
Terrorist attacks	820	0
Attacks on civilian property	1469	0
Kidnapping	38580	4
Damage to civilian property	452	0
Antipersonnel mines	10440	0
Selective killings	184031	4
Forced disappearance	80866	7
Child recruitment to armed groups	18175	5

Table 2. Co-occurrence between other Colombian armed conflict exposure events and conflict-related sexual violence in the National Centre for Historical Memory (NCHM) Database

Armed conflict exposure event	*N*	*N Co-occurrence with sexual violence*	*%*
Torture	9912	1818	18.3%
Physical wounds	13880	1657	11.9%
Child recruitment to armed groups	7756	455	5.9%
Kidnapping	33487	1780	5.3%
Witness to combat	82845	1924	2.3%
Threats	520805	9237	1.8%
Psychological wounds	13949	226	1.6%
Loss of property	120168	996	0.8%
Forced disappearance	160499	759	0.5%
Dispossession of land	31464	160	0.5%
Forced displacement	7540257	29306	0.4%
Murder	919051	2473	0.3%
Forced confinement	75961	192	0.3%
Antipersonnel mines	11250	12	0.1%

Table 3. Co-occurrence between other armed conflict exposure events and conflict-related sexual violence in the Victims Register (RUV) Database

Raw geographic dispersion of sexual violence events

Although location is coded differently in each database (event by specific latitude and longitude in the NCHM Database, registration by municipality in the Victims Register), the two datasets show comparable patterns in terms of areas of high prevalence, as shown in Figure 1.

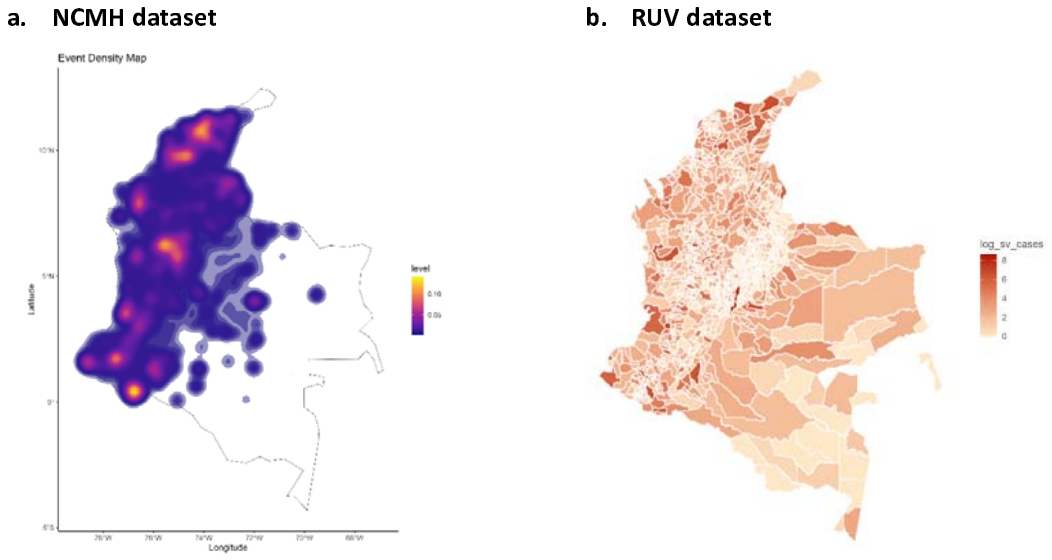

Figure 1. Raw density of total sexual violence events as recorded in **a)** National Centre for Historical Memory database, and **b)** Victims Register by municipio (log scale) in the Colombia armed conflict

Latent geospatial structure of conflict-related sexual violence

Spatial analysis using the log-Gaussian Cox process (LGCP) revealed a latent geospatial structure of sexual violence that was clustered within defined geographic extents (Figure 2), distinct from raw geospatial density (Figure 1). Mesh-based integration weights are shown in Figure S1 of the supplementary material and spatial projections of the latent Gaussian Markov random fields are shown in Figure S4 of the supplementary material.

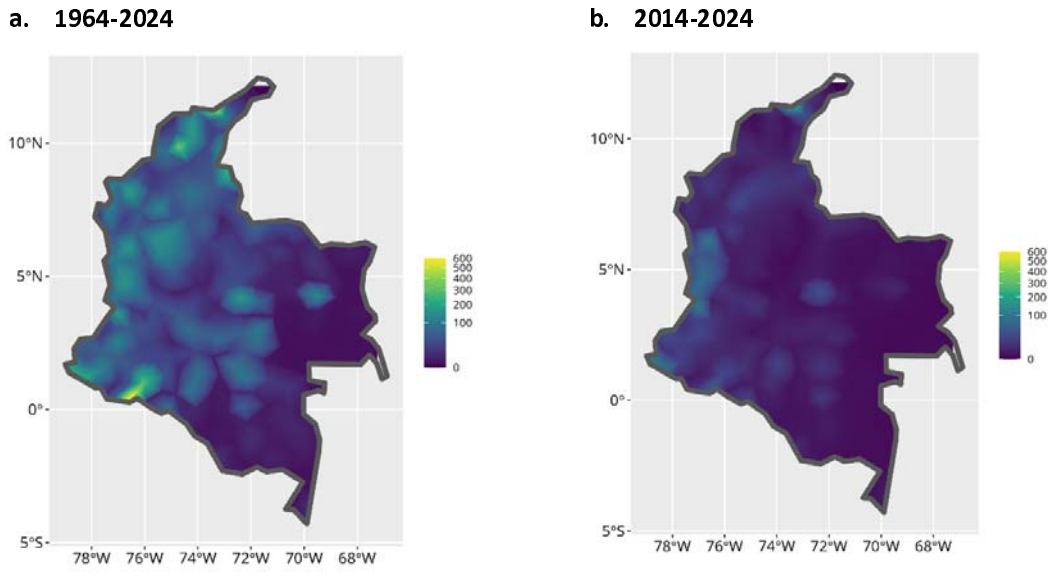

Figure 2. Log-Gaussian Cox Process intensity plot identifying areas of elevated risk for sexual violence for: a) entire duration of the conflict b) 2014-2024, adjusted for population density

For data spanning the entire conflict period (1964-2024), the unadjusted LGCP model estimated significant spatial clustering (β = 2.580; SE = 0.600) with a spatial range of 2.385 km (SE = 0.297) and latent field standard deviation of 2.323 (SE = 0.215). After adjusting for population density, which showed a significant positive association with sexual violence events (β = 0.530; SE = 0.088), the spatial range reduced to 1.733 km (SE = 0.278), and spatial variation declined to 1.783 (SE = 0.152), indicating that population density explained approximately 27% of the spatial range and 23% of unexplained spatial heterogeneity. For sexual violence from 2014-2024, there was a strongly reduced baseline intensity (β = 1.171; SE = 0.570 in the unadjusted model; β = 0.551, SE = 0.385 in the adjusted model), although spatial clustering extended over a wider area (range = 2.523 km in the unadjusted model vs 1.868 km when adjusting for population density). The population density effect remained significant in the recent period (β = 0.458; SE = 0.082), demonstrating the persistent influence of population distribution on the spatial patterning of conflict-related sexual violence throughout the conflict timeline. Full parameters for all LGCP models are shown in Tables S1 and S2 of the supplementary material. Plots for models not adjusted by population density are shown in Figures S1a and S1b of the supplementary material.

Temporal contagion of sexual violence events

Hawkes process modelling of the entire conflict data (1964-2024; Figure 3a) indicated moderate temporal contagion of sexual violence. The Hawkes process with a constant baseline showed a low baseline rate of events ($\mu = 0.009$; SE = 0.001), corresponding to a 0.9% chance of occurrence per day, with modest temporal dependence ($\alpha = 0.186$; SE = 0.011). The decay rate ($\beta = 0.188$; SE = 0.011) suggested that the contagion effect was time-limited, with a half-life of approximately 3.7 days ($\ln(2)/\beta$). The branching ratio ($\alpha/\beta = 0.989$) indicates a near-critical process, where each event generates, on average, just under one additional event. When adjusting for non-homogeneous baseline rate, there was a stronger immediate increase in intensity for subsequent events ($\alpha = 1.283$; SE = 0.040) but the decay rate ($\beta = 3.757$; SE = 0.117; half-life = 0.18 days) was below the 1-day temporal resolution of the data due to the 1-day artificial jitter added to prevent simultaneous events, meaning any temporal contagion effect occurred over less than a day, suggesting negligible temporal contagion when background rate changes are accounted for.

For Hawkes process modelling of sexual violence events from 2014-2024 (Figure 3b), the constant baseline model showed a lower baseline rate ($\mu = 0.007$; SE = 0.003), corresponding to a 0.7% daily chance of occurrence, with lower temporal contagion ($\alpha = 0.069$; SE = 0.010) and a longer decay rate ($\beta = 0.069$; SE = 0.010; half-life = 10.04 days). The branching ratio ($\alpha/\beta = 1.000$) indicated near-critical dynamics, where each event increases the expected rate of subsequent events by approximately one additional event. The model adjusted for changing baseline rates revealed higher immediate intensity increases ($\alpha = 0.537$; SE = 0.068) but a decay rate below the 1-day temporal resolution of the data ($\beta = 2.843$; SE = 0.367; half-life = 0.24 days), suggesting negligible temporal contagion when background rate changes are accounted for. Comparison between conflict periods reveals a weakening of temporal contagion over time, with sexual violence events in recent years appearing less clustered and more independent once broader fluctuations in conflict intensity are accounted for.

Discussion

We report a population-scale profile of sexual violence within the Colombian armed conflict using complete data from the statutory Register of Victims and the National Centre for Historical Memory (NCHM) database of armed conflict victimisation. Victims of sexual violence were overwhelmingly female and disproportionally from minority ethnic groups. Sexual violence was more likely to co-occur with types of armed-conflict-related violence which more directly targeted individuals. Geospatial analysis revealed that sexual violence

exhibited significant geographic clustering with distinct temporal patterns across conflict periods. For the entire conflict period, there was high event density clustered within relatively confined geographic ranges. In contrast, during 2014-2024 there was reduced spatial intensity and broader geographic clustering. Analysis of temporal contagion of events indicated that event dependence was largely driven by changes in background rate because, when background rate was adjusted for, the event-to-event temporal contagion was minimal – decaying in less than 1 day, indicating that structural and contextual influences rather than incident-specific characteristics drive temporal contagion. These findings suggest that sexual violence patterns in the Colombian armed conflict have become geographically more dispersed in recent years with reduced temporal contagion effects, indicating potential changes in conflict dynamics and perpetration over time.

Research on the perpetration of sexual violence by armed groups indicate that it is not an inevitability of armed conflict but subject to group norms, leadership, conflict dynamics, and broader political conditions (Nordås & López, 2025). These may have changed significantly in recent years. Since the height of the Colombian armed conflict, the reduction in violence has been accompanied by a fragmentation of armed groups with less concentrated areas of control with influence is spread more thinly across wider territories (Albarracín et al., 2023; Tkacova et al., 2023). This may explain the transition from higher-intensity, geographically focused patterns of sexual violence, potentially more associated with it occurring as part of combat operations, to broader clustering with less intense and shorter-lived temporal contagion, potentially reflecting its relationship with longer-term territorial control and community subjugation, as well as a reaction to public recognition and condemnation (Blanco Blanco et al., 2021; Fiscó, 2005).

Here, geographic clusters of armed-conflict-related sexual violence indicate priority areas for provision of services for victims. Clinical response to sexual violence requires emergency and post-acute care (Alexander & Miller, 2022) as well as long-term support services (Golding, 1999; Santaularia et al., 2014). Barriers relating to stigma, fear and health service preparedness may also delay service engagement (Zinzow et al., 2022). We note the geographic clustering of sexual violence covers large cities, where health services are concentrated in Colombia, as well as rural areas and small towns, including those where control is disputed between armed actors. This makes the equitable provision of healthcare a significant challenge due to problems with access, resources, and active interference by

armed groups that particularly affect services related to women's health and sexual violence (Lilja et al., 2024; Ramos Jaraba et al., 2020).

Colombia's national PAPSIVI programme (an acronym from its Spanish language title *Programa de Atención Psicosocial y Salud Integral a Víctimas*, in English "Psychosocial Care and Comprehensive Health Program for Victims") provides healthcare and psychosocial support to victims of the armed conflict nationally. Analysis of service data indicates it successfully provides priority access with appropriate support provision to victims of the conflict registered as experiencing sexual violence (Constable Fernandez, Acosta-Ortiz, García Durán, Pappa, et al., 2025; Constable Fernandez, Acosta-Ortiz, García Durán, Saunders, et al., 2025) although clinical and social outcomes, and the extent to which victims of sexual violence who have not registered as such, are being successfully supported, is currently unknown.

By comparing Hawkes process models with and without baseline adjustment, we identified that temporal contagion is largely driven by slower-moving trends in sexual violence likely driven by structural factors associated with broader conflict dynamics, rather than short-term event-to-event contagion more associated with incident-specific characteristics. Immediate intervention to prevent further incidents of sexual violence may be practical in some situations. However, these results suggest that depending solely on a policy of reactive intervention is unlikely to be the most successful strategy for prevention of armed-conflict-related sexual violence in the Colombian context because the temporal window for preventing local contagion effects may be very small – estimated at below 1 day in our study. To address these, social and structural interventions focused on prevention may be more appropriate. Indeed, interventions to reduce sexual violence by armed groups in conflict settings have focused on exactly these processes – including reducing potential victims' exposure to situations that would allowed opportunistic violence, increasing women's autonomy and reducing economic dependence, reducing impunity and the perception of impunity through improved legal accountability, and deploying public campaigns aimed at increasing awareness and reducing acceptance of sexual violence (Spangaro et al., 2013). None, to our knowledge, have been trialled in Colombia, indicating an opportunity for a preventative public health approach.

We note some limitations of this study. With regard to the demographic data, the profile of victims is relatively consistent across data sources with some notable differences. Victims in the Register of Victims were older than victims in the NCHM database, likely due to the fact that while the NCHM database records specific events, the Register of Victims is a record of victims' registrations, who may register several years after experiencing sexual violence. There is a higher proportion of victims from ethnic minorities in the Register of Victims, potentially reflecting its sole reliance on self-registration rather than a third party reports, the latter of which may be more limited in areas with large populations of primarily Indigenous and Afrocolombian populations.

In addition, conflict-related sexual violence is likely under-reported and under-detected with good evidence that this is the case in Colombia (Otero & Melo, 2017). Nevertheless, different national data sources, including crime reporting, armed conflict victim registrations, and multi-source identification, tend to show similar relative changes in incidence in sexual violence that track changes in the intensity of the conflict indicating they may be sampling a similar population (Castillejo Cuéllar et al., 2022). Nonetheless, the extent to which there are specific groups who are more likely to have incidents of sexual violence remain unrecorded remains unclear. Those in areas of active conflict (Bahamón et al., 2009), displaced women (Wirtz et al., 2014), sexual and gender minorities (Díaz Botia, 2014), and people from ethnic minorities (Marciales Montenegro, 2015) have been identified as facing particular structural barriers in reporting sexual violence and accessing care.

We also note the diversity of sexual violence may not be well accounted for by the single coding of 'sexual violence' used in this study. Sexual violence may variously include rape, forced prostitution, sexual slavery, forced abortion, forced nudity, or sexual assault, to name but a few relevant criminal acts (Koos, 2017) and it is likely there may be different geographical spread and dynamics that depend on the specifics of these acts.

In conclusion, the trajectory of sexual violence in the Colombian armed conflict reflects a shift from geographically concentrated, high-intensity incidents toward more diffuse patterns, with clear areas of high historical prevalence where victim support remains essential. The temporal dynamics of sexual violence suggest that interventions that proactively address structural and long-term contextual determinants may be an important component of prevention.
