Abstract

The physicochemical environment of the gut, particularly colonic pH, plays a critical role in shaping host-microbe interactions; yet its influence on systemic immunity in humans remains poorly understood. Here, we integrated faecal metagenomics, plasma short-chain fatty acid (SCFA) profiling, SmartPill wireless pH-motility capsule data, and deep immunophenotyping of peripheral blood mononuclear cells in a cross-sectional study of 54 healthy participants to investigate the relationship between colonic pH, microbial metabolism, and immune tone. We found that lower colonic pH was associated with cytokine-producing $CD8^+$ T cells, while higher pH correlated with pre-exhausted $CD8^+$ T cells and elevated neutrophil populations. Metagenomic analyses revealed species-level associations within the genus *Eubacterium*, linked to colonic pH and peripheral immune profiles. These findings suggest that microbial metabolic activity and gut pH may work together to jointly modulate immune tone beyond the gut in humans, establishing a functional axis between microbial fermentation, physicochemical gut conditions, and systemic immunity.

Introduction

The gastrointestinal (GI) tract orchestrates tightly regulated physiological gradients, among which pH plays a central role in shaping microbial[1] and immune dynamics[2]. pH dynamics across the GI tract are markedly heterogenous[2,3]. The large intestine presents a mildly acidic to neutral pH (5.5–7), with the proximal colon maintaining a more acidic environment (pH ~5.5-6.0), whereas the distal colonic luminal pH is typically more alkaline (~6.5-7.0)[4,5]. This spatial variation parallels the distribution of the gut microbiota[6-8]. Microbial density is low in the upper GI tract but peaks in the colon, which harbours the most diverse and metabolically active communities, thus serving as a key site for host-microbiota interactions[9,10].

Colonic pH is shaped by microbial metabolic activity[11,12], while pH itself influences the composition and activity of the gut microbiota[13,14]. This bidirectional interaction, therefore, tightly links microbial function with the physiochemical environment of the colon.[1] Diet is a key modulator of this interaction; diets rich in complex carbohydrates such as fibre, for example, enhance microbial diversity and fermentation, leading to the production of short-chain fatty acids (SCFAs)[15,16]. These acidic metabolites lower colonic luminal and interstitial fluid pH[17], making colonic pH a dynamic parameter responsive to both microbial and dietary inputs.

The GI tract is also a major immunological organ[18], with extensive crosstalk between resident microbes and host immunity. Studies using germ-free animal models revealed that the gut microbiota is essential for the maturation of both intestinal and systemic immunity[19,20], leading to impaired lymphoid tissue development and T cell function, and reduced immunoglobulin production[21-23]. Yet, most mechanistic insights have largely centred on mucosal immunity[24] and experimental models. The extent to which the gut microbiota shapes the peripheral immune system in humans remains poorly understood.

Here, we present an integrated systems-level analysis of host microbiota–intestinal pH–immune interactions in a human cohort, driven by the hypothesis that lower colonic pH encourages a more anti-inflammatory peripheral immune phenotype facilitated through microbiota-derived metabolic activity. By combining faecal shotgun metagenomic sequencing, *in vivo* colonic intraluminal pH profiling using the SmartPill wireless pH-motility capsule, and deep immunophenotyping of peripheral blood mononuclear cells (PBMCs), our findings indicate that colonic pH may indeed have an important immunomodulatory effect on the peripheral immune system. In particular, *Eubacterium* species and their metabolic input in amino acid and nucleotide metabolism and biosynthesis pathways may contribute to peripheral immunomodulation, suggesting colonic pH may be a functional mediator of microbiota-systemic immune crosstalk.

Results

Mapping colonic pH gradients using a wireless pH-motility capsule (SmartPill)

Fifty-four healthy participants completed the trial, of whom 41% were female. Participants had a mean age of 49 ± 12.9 years and body mass index (BMI) of 27.0 ± 3.7 $kg \cdot m^{-2}$ (Figure 1, Table S1). The SmartPill software provides median, minimum, and maximum pH values – these provide proxy values for different intestinal sites. The minimum colonic value indicates the ascending colon, while the maximum colonic pH indicates distal colonic and sigmoid/rectum pH (Figure 2A-B). To map the heterogeneity of luminal pH across different colonic regions, we divided the colon into four equal quartiles, as previously reported[10]. This was performed based on transit time by dividing the total time in the colon into four equal quartiles, with the assumption that transit time would have been the same across all segments of the colon. These quartiles are thought to approximately correspond to the main regions of the large intestine (Figure 2A). Indeed, our data fitted with the expected pattern of pH

distribution along the colon (Figure 2B), whereby colonic minimum pH was significantly correlated with first and second quartile intraluminal pH (Figures 2C-D), colonic median pH was significantly correlated with first to third quartiles (Figures 2E-G), and colonic maximum pH was correlated with second to fourth quartiles (Figures 2H-J).

Colonic pH correlates with peripheral immune cells and SCFAs

Gut transit time is an important physiological variable that integrates nutrient absorption and microbial fermentation[25], thus its link with intraluminal pH represents an interesting avenue for investigation. Longer whole-gut (WGTT), small and large bowel (SLBTT) and colonic transit time (CTT) were associated with higher (more basic) pH in quartiles two through four, but not quartile one (Figure 2K). Strikingly, higher daily dietary fibre intake was associated with lower, or more acidic, minimum and quartile one colonic pH (Figure 2K). The main by-product of fermentable fibre produced by the gut microbiota inhabiting the large intestine is SCFAs[26], acidic immunomodulatory metabolites that can profoundly influence physiological outcomes such as colonic pH[17]. Only higher plasma propionic acid levels were associated with lower quartile one, two and four colonic pH (Figure 2K).

We further analysed potential relationships between colonic pH and 121 peripheral immune cell populations and sub-types, including activation and cytokine expression across these cell types. We identified varying associations with 14 different peripheral immune cell subsets across all seven colonic pH variables (Figure 2K). Overall, these suggest that colonic pH may be associated with peripheral immunomodulation. Notably, 10 associations were with the T cell lineage; for example, elevated numbers of $CD8^+$ central memory T cells and a dual cytokine-producing (interferon-γ [IFNγ]/ tumour necrosis factor-α [TNFα]) population of activated $CD8^+$ T cells were associated with lower colonic minimum pH. Conversely, programmed cell death protein-1 $(PD\text{-}1)^+$ $CD8^+$, activated $PD\text{-}1^+$ $CD8^+$ T cells, IFNγ-

producing natural killer (NK) cells and neutrophils were associated with more basic colonic pH.

Correlation analyses between plasma SCFA levels and the peripheral immune system further revealed 17 significant associations, of which 14 were negatively associated with isovaleric acid and were comprised almost entirely of $CD4^+$ T cell subsets (Figure S1). Plasma butanoic acid was positively associated with B cells and PD-1^+ $CD8^+$ T cells, whilst lower plasma acetic and butanoic acid were associated with the production of both interleukin (IL)-2 and TNFα by $CD161^+$ $CD4^+$ T cells (Figure S1).

A distinct subset of pre-exhausted $CD8^+$ T cells consistently underpins gut microbiota and colonic pH associations

Upon persistent antigen stimulation, such as during chronic infection or cancer, activated T cells can enter a state of functional decline known as exhaustion[27,28]. This transition is marked by sustained expression of inhibitory receptors, including PD-1 and TIM-3, and diminished proliferative capacity, often linked to impaired IL-2 signalling and reduced cytokine production (i.e., TNFα and IFNγ)[29-31] (Figure S2A). For example, in melanoma patients, TIM-3^+ PD-1^+ tumour-specific $CD8^+$T cells were more dysfunctional than TIM-3- PD-1^+ and TIM-3- PD-1- T cells, producing less IFN-γ, TNF-α and IL-2[30]. However, T cells can enter a transitional pre-exhausted state, typically marked by reduced IL-2 production and consequently diminished proliferative capacity[32]. This state is characterized by elevated PD-1 expression in the absence of other inhibitory receptors such as TIM-3[33], while retaining functional competence and the ability to produce effector cytokines[34,35] (Figure S2A). We performed a sensitivity analysis focusing on the functionality of PD-1^+ $CD8^+$ T cells and found that these cells retained a pre-exhausted phenotype, as evidenced by a lack of TIM-3 and IL-2 expression (Figure S2B). Moreover, taxonomic profiling identified 14 differentially

abundant taxa specifically positively associated with these pre-exhausted $CD8^+$ T cells (Figure S2C).

Colonic pH across anatomical segments is associated with the gut microbiota and associated metabolic pathways

To assess differences in the gut microbiota in relation to colonic pH measurements, we calculated α- and β-diversity metrics from shotgun metagenome data. We found no association between α-diversity and colonic pH (Table S2). However, β-diversity analyses revealed distinct gut microbiota differences across colonic pH in quartile one (Table S2). Specifically, based on unweighted UniFrac distances, quartile one colonic pH explained 3.5% of the observed variation in the gut microbiota composition (P=0.014, Table S2), suggesting compositional differences characterised by the presence/absence of unique microbial taxa.

Taxonomic profiling analysis revealed that one bacterial species, *Blautia schinkii*, was associated with colonic pH in quartile four (q=0.0143; Figure S3). Functional profiling analysis revealed 169 positive associations between differentially abundant species-specific metabolic pathways and quartile four (Figure 3A). Eighty metabolic pathways, categorised by biological function, were stratified across eight bacterial species (Tables S3-S4, Figure 3A). Notably, we did not identify any significant *Blautia schinkii*-specific metabolic pathways associations with quartile four colonic pH. Our analysis instead showed that *Bifidobacterium pseudocatenulatum*, a species that thrives on complex carbohydrate fermentation[36], exhibited the strongest associations across all seven classifications of metabolic pathways, particularly with pathways involved in amino acid biosynthesis.

Gut microbial species and metabolic pathways are associated with the peripheral immune system

Next, we sought to identify specific taxa and microbial pathways associated with the peripheral immune system. Sixty two taxa, grouped at the genus level, were associated with 64 immune cell populations/sub-types, stratified by immune subset categories, resulting in 380 associations in total (Figure 3B, Tables S5-S7). Although associations were present across all immune groups, associations stemming from the $CD4^+$ and $CD8^+$ T cell categories prevailed. Notably, these clusters were predominantly composed of single and double pro-inflammatory cytokine-producing early and late-activated populations ($CD69^+$ and human leukocyte antigen-DR isotype $[HLA\text{-}DR]^+$, respectively), as well as $PD\text{-}1^+$ expressing cells amongst others (Tables S5 and S7). We also identified that differentially abundant taxa classified as 'Other' exhibited the strongest associations with both $CD4^+$ and $CD8^+$ T cell clusters, followed by the genus *Merdicola*, comprising two unique, genetically similar bacterial taxa *Merdicola sp001915925* and *Merdicola sp900555085* (Table S5). Taxa grouped into the 'Other' category also predominated in associations with the peripheral immune system overall, comprising taxa yet to be characterised (Tables S5-S6). Specifically, out of eighty associations in total, *GGB3612 SGB4882 (COE1 sp001916965)* is the most prevalent, with sixteen associations spanning innate, NK, CD4□, and CD8□ T cell categories (Table S5). At the functional level, 945 species-specific metabolic pathway associations were identified with the peripheral immune system, linked by eight bacterial species (Figure 3C and Table S8). Thirty-five metabolic pathways, categorised based on biological function, were associated with 60 peripheral immune cell populations/sub-types (Tables S4, S7 and S8). Consistently, $CD4^+$ and $CD8^+$ T cell clusters showed the largest and strongest associations, again predominated by subsets including single (i.e., IFNγ, IL-17A and TNFα) and double (i.e., IFNγ/TNFα IL-2/TNFα) pro-inflammatory cytokine-producing activated cell

types (Figure 3C & Tables S7-S8). Moreover, pathways involved in nucleotide metabolism and biosynthesis had the most pronounced associations across the peripheral immune system (Figure 3C, Tables S4, S7 and S8). Among the species identified as differentially abundant in the taxonomic profiling analysis, four remained consistent, linking the peripheral immune system and bacterial metabolic output: *Clostridium sp AM22 11AC*, *Eubacterium ventriosum*, *Holdemanella biformis* and *Streptococcus thermophilus*. We identified that *Holdemanella biformis* exhibited the highest functional metabolic contribution across all pathway groups (excluding lipid and membrane metabolism) and accounted for the greatest number of associations with the peripheral immune system (Figure 3C).

Holdemanella biformis **and its metabolic pathways are associated with the peripheral immune system**

To delineate this further, we explored the relationship between *Holdemanella biformis,* formally *Eubacterium biforme*[37], which was prevalent in 18.5% of the cohort, and the peripheral immune system more closely, revealing positive associations with 11 peripheral immune cell types (Figure 4A). More than 50% of associated immune cells were T cell subsets, specifically IL-17A-producing and PD-1^{+} CD4^{+} and CD8^{+} T cells. Strikingly, we identified two natural killer (NK) cell populations producing TNFα, a well-characterised pro-inflammatory cytokine that reportedly governs whether *Holdemanella biformis* drives inflammation or resolution[38]. Moreover, we demonstrated that the functional metabolic activity of *Holdemanella biformis* spans 37 pathways and exhibited varying positive associations with 21 peripheral immune cell populations and sub-types, 11 of which correspond to the immune subsets identified via taxonomic profiling (Figure 4B). Among these, four pathways consistently prevailed with the strongest associations across the suite of immune cell subsets; the methylerythritol phosphate pathway I, superpathway of L-tyrosine

biosynthesis and superpathway of thiamine diphosphate biosynthesis III, as well as the flavin biosynthesis I pathway being associated with 18 and 19 subsets, respectively (Figure 4B).

***Eubacterium*-specific metabolic pathways emerged as the shared feature of colonic pH in quartile four and the peripheral immune system**

To investigate the interplay between colonic pH, gut microbiota, and the peripheral immune system, we compared the taxonomic and functional profiling results to identify any shared features. This revealed a genus-level convergence centred on *Eubacterium*, with distinct species showing differential associations across biological domains (Figure 5). *Eubacterium ventriosum*, which had a prevalence of 25.9% in the cohort, consistently linked to peripheral immune cell profiles, suggesting a potential relationship with systemic immune modulation. In contrast, *Eubacterium rectale* and *Eubacterium sp CAG 38* were associated with colonic pH in quartile four. Specifically, taxonomic differential abundance analysis showed that three immune cell types, C-C chemokine receptor type 7 $(CCR7)^+$, central memory (CM) $CD8^+$ T cells, and non-classical monocytes, were positively associated with *Eubacterium ventriosum* (Figure 5A). These remained prominent amongst 13 other peripheral immune cell types positively associated with metabolic pathways of *Eubacterium ventriosum* (Figure 5B). Notably, non-classical monocytes exhibited the strongest and largest associations with 15 of the 16 metabolic pathways, whilst the purine ribonucleoside degradation pathway had the highest number of associations across the suite of immune cell subsets, predominated by pro-inflammatory T cell subsets including IL-17A-producing and PD-1 expressing $CD4^+$ and $CD8^+$ T cells, as well as TNFα-producing NK and T cell populations (Figure 5B).

Whilst we did not identify any *Eubacterium ventriosum*-specific metabolic pathway associated with colonic pH, we profiled another two metabolically active *Eubacterium* species (Figure 5C). *Eubacterium rectale* facilitated the positive association between colonic

pH in quartile four with the D-galactose degradation, or Leloir, pathway. In contrast, *Eubacterium sp CAG 38*-specific pathways, including those involved in amino acid and nucleotide biosynthesis, accounted for the remaining positive associations with quartile four (Figure 5C).

To better elucidate the biological relevance of these findings, we examined overlapping pathways across both functional analyses and found that the metabolic activity of *Eubacterium sp CAG 38* and *Eubacterium ventriosum* involved in the L-valine (amino acid) biosynthesis pathway and the purine ribonucleoside degradation and UMP biosynthesis II and III pathways, classed as nucleotide metabolism and biosynthesis pathways respectively, linked colonic pH in the fourth quartile and the peripheral immune system (Figure 6). Twelve cell types prevailed, reinforcing a more pro-inflammatory profile characterised by IL-17A-producing $CD4^+$ T cells, non-classical monocytes and TNFα-producing NK and T cell subsets, all of which have been consistently reported throughout. Additionally, PD-1-expressing T cells, particularly $CD8^+$ T cells, repeatedly emerged as a recurrent feature.

Discussion

While the gut microbiota is known to influence mucosal immunity, its impact on systemic immune tone via physicochemical cues such as colonic pH remains poorly defined in humans. A pilot study using 16S ribosomal RNA sequencing showed that baseline frequencies of 10 circulating T cell subsets were associated with shifts in bacterial genera over 6 weeks, suggesting links between peripheral immunity and microbial dynamics.[39] Building on this, we deeply phenotyped the gastrointestinal pH using real-time monitoring with the SmartPill device, the gut microbiota using metagenome sequencing, and the immune system using flow cytometry to characterise 121 subtypes and activation markers. We demonstrated that both colonic luminal and regional pH were associated with peripheral

immunomodulation. Specifically, lower colonic luminal pH was associated with the enrichment of T cell populations, particularly $CD8^+$ T cells, including cytokine-producing and pre-exhausted phenotypes. A more acidic colonic pH, primarily driven by SCFA production from fibre fermentation[17], may foster a metabolically active gut environment[1] that supports functional $CD8^+$ T cell responses. These cells, traditionally recognised for their role in antiviral and cytotoxic responses[40,41], are highly responsive to environmental cues such as microbial-derived metabolites and inflammatory cytokines[42-44]. These environmental cues can potentiate $CD8^+$ T cell effector responses and enhance the secretion of key pro-inflammatory mediators including IFNγ and TNFα[45-47]. In contrast, a more alkaline pH, typically associated with depletion of fibre substrates for fermentation and reduced SCFA levels[17], may favour PD-1^+ exhausted-like $CD8^+$ phenotypes, linked to chronic diseases such as cancer[28,48] and high blood pressure[49]. Additionally, higher neutrophil counts were associated with a more alkaline colonic pH[50], commonly observed in metabolic syndrome[51]. Together, these findings suggest that colonic pH, shaped by the gut microbiota and microbial fermentation, may serve as a functional cue for peripheral immune activation, linking gut metabolic tone to systemic immune outcomes.

A key finding was *Eubacterium* species mediating the link between colonic pH and peripheral immune responses in humans. This genus, a core component of the human gut microbiota, exhibits widespread colonisation across diverse populations spanning Africa[52], Australia[53], Europe[54], Asia[55] and the Americas[56,57]. Our analyses revealed that, while functionally distinct, *Eubacterium sp CAG 38* and *Eubacterium ventriosum* metabolically converge in the L-valine biosynthesis pathway, which emerged as the only shared metabolic feature associated with colonic pH (i.e., quartile 4) and 11 peripheral immune cells, 7 of which are T cell subtypes. Valine, an essential branched-chain amino acid, serves as a fundamental protein building block and an immunomodulatory metabolite[58]. L-valine

enhances PI3K/Akt1 signalling in macrophages[59], key antigen-presenting cells of the innate immune system[60]. Pharmacological inhibition of PI3K partially attenuates L-valine-induced bacterial phagocytosis[59], aligning with prior evidence that PI3K/Akt signalling governs macrophage phagocytic function[61,62]. Notably, we observed a strong association with non-classical monocytes, precursors of macrophages, which also present antigen-processing capabilities under inflammatory conditions[63]. Moreover, altered valine tRNA biogenesis augments mitochondrial energy production in T cell acute lymphoblastic leukemia[64], underscoring valine's broader role in supporting immune cell bioenergetics across both innate and adaptive compartments. These findings suggest that *Eubacterium*-derived valine metabolism may represent a mechanistic bridge between gut physicochemical gradients and systemic immune tone.

In parallel, both species showed strong associations with the purine ribonucleoside degradation pathway. Uric acid, the end product of purine metabolism[65], can accumulate in response to diets high in purine-rich foods (i.e., red meat, seafood) or low in fibre, shifting microbial activity toward increased uric acid production[66]. As a recognised damage-associated molecular pattern[67,68], uric acid activates antigen-presenting cells – including monocytes/macrophages and dendritic cells – prompting the upregulation of co-stimulatory molecules such as CD80 and CD86[69]. This enhanced expression facilitates the activation of $CD8^+$ T cells, driving their proliferation and effector function[70,71]. Conversely, pharmacological inhibition of uric acid production suppresses $CD8^+$ T cell activation and effector function, as evidenced by reduced CD69 and IFN-γ expression, respectively, and proliferative capacity due to diminished secretion of IL-2[72]. These findings suggest that sustained upregulation of *Eubacterium ventriosum*-mediated purine catabolism may elevate uric acid levels, contributing to the altered $CD8^+$ T cell landscape we observed, such as loss of IL-2 production in the PD-1^+ $CD8^+$ T cells consistent with a pre-exhausted phenotype.

Under physiological conditions, PD-1 is transiently induced upon T cell activation to limit excessive T-cell receptor signalling and maintain immune homeostasis[73]. Under conditions of chronic infection and cancer, however, persistent antigen exposure drives sustained PD-1 expression on $CD8^+$ T cells, contributing to their progressive functional exhaustion[27,28,74]. In cancer, exhausted T cells accumulate within the tumour microenvironment, and are a key target of immune checkpoint blockade[48]. For example, therapeutic inhibition of PD-1 and its ligand PD-L1, otherwise known as the PD-1/PD-L1 axis[75], has shown clinical efficacy in numerous types of cancer and acts primarily by reinvigorating effector function and restoring anti-tumour immunity[76,77]. Importantly, butyrate-producing bacteria, such as those from the *Eubacterium* genus[85,86], including *Eubacterium R sp003526845*, which we identified as differentially abundant, can modulate the epigenetic and metabolic programming of $CD8^+$ T cells, thereby influencing the expression of exhaustion markers such as PD-1[78]. Through enhanced histone acetylation and improved mitochondrial function, butyrate supports effector activity and mitigates terminal exhaustion, ultimately enhancing responsiveness to PD-1 checkpoint blockade[79-81]. This may underlie the positive correlation we observed between PD-1^+ $CD8^+$ T cells and plasma butanoic acid levels, and may explain why these profiled PD-1^+ $CD8^+$ T cells remain functional (i.e., IFNγ-producing) and are not terminally exhausted. Butyrate also plays a potent role in regulating neutrophil activity by suppressing inflammation through pathways such as GPR43 signalling[82,83]. Consequently, reduced SCFA levels, often indicated by a more alkaline colonic pH, may contribute to the elevated neutrophil counts observed.

Another key finding concerned *Holdemanella*, which has been associated with improved outcomes in inflammatory bowel disease and immune checkpoint inhibitor-associated colitis[84]. *Holdemanella biformis* is a well-characterised producer of SCFAs, particularly butyrate, and has been reported to exhibit both anti-inflammatory and anti-tumorigenic

properties in the gut[85,86]. However, our analysis revealed a strong functional association with the L-tyrosine biosynthesis pathway, a metabolic pathway recently implicated in microbial adaptation to dietary fibre deficiency[87,88]. Importantly, increased L-tyrosine biosynthesis enhances microbial tyrosine fermentation, leading to elevated *p*-Cresol production[89]. This microbial metabolite is subsequently conjugated in the host to form uremic toxins such as *p*-Cresol sulphate and *p*-Cresol glucuronide, both of which have been implicated in systemic toxicity, chronic kidney disease[90,91], and elevated blood pressure in humans[87].

While these findings offer important insights, certain limitations cannot be overlooked, most notably, the small cohort size. The colonic quartiles were calculated based on transit time, not on geographical locations; thus, they represent proxy sites rather than the exact colonic regions we attempted to characterise. This underscores the need for novel technologies capable of capturing more precise, spatially resolved pH profiles across both luminal and tissue microenvironments. Following on from this, while faecal samples remain the most readily obtainable specimen for evaluating the human gut microbiota, they do not accurately reflect region-specific microbial communities; thus, such devices would also ideally enable concurrent sampling of region-specific microbiota, facilitating a more integrated understanding of host–microbiota interactions within distinct gut niches. Therefore, our findings regarding quartile four regional colonic pH were not unexpected, as quartile four is most directly reflective of the rectum and, therefore, of the faecal microbiota from which metagenomic sequencing was performed. Nonetheless, our study has several strengths, including a similar representation of males and females and the use of an *in vivo* system to capture in detail the pH of the human GI tract. The device employed in this study is no longer commercially available, and no current alternatives offer comparable resolution or functionality. This renders our dataset both unique and timely, providing a valuable reference point for future investigations into gut physicochemical-immune axes in humans.

In conclusion, our findings indicate a potential physiological axis linking gut microbial composition, colonic intraluminal pH, and the production of fibre-derived metabolites to systemic immune modulation in humans. This coordinated interplay supports that local gut environmental cues, particularly those shaped by microbial fermentation and physicochemical gradients, can exert far-reaching effects on peripheral immune tone. These insights advance our understanding of how the gut microbiota and associated microbial metabolism, and gut pH converge to regulate human immunity, with implications for the design of microbiota-targeted interventions in immune-mediated and inflammatory diseases.

Materials and Methods

The pH of Intestines and Blood-pressure Regulation (pHibre) cohort

The pH of Intestines and Blood-pressure Regulation (pHibre) study was approved by the Monash University Human Research Ethics Committee (Study ID: 23336) and followed the Declaration of Helsinki. All participants provided written consent. The study was registered with the Australian New Zealand Clinical Trials Registry under registration number ACTRN12620000284965. Recruitment of male and female volunteers was conducted between June 2020 and October 2021 through study advertisement. Inclusion criteria included body mass index (BMI) between 18.5–35 kg/m^2 and age between 18-70 years old. Exclusion criteria included non-English speaking; gastrointestinal disorders and diseases (including history of intestinal surgery, lactose intolerance, inflammatory bowel disease, celiac disease, chronic pancreatitis or other malabsorption disorder); gastrointestinal surgery in the last 3 months; type 1 or 2 diabetes; chronic kidney disease; swallowing disorders or severe dysphagia to food or pills; having implanted or portable electro-mechanical devices; and recent use of antibiotics (< 3 months) or probiotics (< 6 weeks). The recruitment summary is outlined in Figure 1A. Study outcomes are described in detail in the following sections and are summarised in Figure 1B. Briefly, the study included one visit during which a fasted blood sample was collected for subsequent plasma SCFA quantification and PBMC isolation, and measurement of fasting blood glucose (Table S1), followed by ingestion of the wireless pH-motility capsule (SmartPill) to measure transit time and pH[92]. The mean whole-gut transit time was 32.8 ± 17.6 hours. Participants also provided a faecal sample and self-assessed stool consistency using the Bristol Stool Form Scale (BSS)[93], with a median reported BSS stool classification of type 4 (Table S1).

Habitual dietary records

Participants completed a three-day food diary leading up to the appointment, on one weekend day, and on two weekdays to assess habitual intake. The dietary information was then analysed through a nutritional analysis software, FoodWorks 10 (Xyris, Queensland), using an Australian food composition database for energy, macro- and micronutrient intake (Table S1).

Wireless pH-motility (SmartPill) capsule data collection

Fasting participants consumed a standardised low-fat and low-fibre muesli bar to facilitate gastric motility and support capsule passage, followed by ingestion of the SmartPill™ Motility Testing System (Medtronic). After being swallowed, the SmartPill™ measured in real-time, the intraluminal pH, pressure, and temperature as it travelled through the gastrointestinal tract. The information was transmitted wirelessly to a portable receiver worn by the participants until excretion, indicated by a signal loss from the device coinciding with the passage of stools. GI transit times and pH data were independently determined from the Smart Pill™ data by at least two trained investigators.

Peripheral blood mononuclear cell (PBMC) isolation & flow cytometry

PBMCs were isolated by density-gradient centrifugation, cryopreserved, and later thawed for flow cytometry. Briefly, cells were stimulated with phorbol 12-myristate 13-acetate (PMA; Sigma-Aldrich, 16561-29-8) and ionomycin (Sigma-Aldrich, I0634) followed by treatment with brefeldin A (eBioscience™ Brefeldin A Solution (1000X), 00-4506-51) and monensin (eBioscience™ Monensin Solution (1000X), 00-4505-51) for intracellular cytokine accumulation. Cells were then stained with ViaDye Red Fixable Viability Dye (Cytek Biosciences, R7-60008), followed by surface antibody marker staining (Table S9). Cells were fixed with the Foxp3/Transcription Factor Staining Buffer Kit (Sapphire Bioscience, TNB-

0607-KIT) and then subjected to intracellular staining (Table S9). Full protocols, reagent details, and preparation conditions are provided in the Supplementary Methods. Samples were acquired on a Cytek Aurora 5 Laser Spectral Analyser at the FlowCore Facility of Monash University. Data was analysed using FlowJo v10.10.0, and gating strategies are outlined in Table S10.

Plasma short-chain fatty acid (SCFA) measurements

Fasting blood was collected in the morning, and plasma SCFAs were quantified using mass spectrometry as previously described[94]. Briefly, 20 µl of plasma was analysed in duplicates in a Q-Exactive Orbitrap mass spectrometer (Thermo Fisher Scientific) in conjunction with a Dionex UltiMate 3000 RS high-performance liquid chromatography (HPLC) system (Thermo Fisher Scientific). We accepted a coefficient of variability <15%. Standard curves were constructed using the area ratio of the target analyte, and the internal standard in the range of each analyte was used. The levels of acetic (n=1), butanoic (n=3), isobutanoic (n=2), valeric (n=1), isovaleric (1) and propionic acid (n=9) were below detection level of the standard curve; in this case, they were considered half of the lowest measurable value (equivalent to 0.025 ng ml−1).

Faecal DNA extraction and high-throughput shotgun-metagenomic sequencing

The STORMS (Strengthening the Organization and Reporting of Microbiome Studies) reporting guidelines were followed throughout[95,96]. Participants collected stool samples at home in tubes containing DNA/RNA Shield (Zymo Research, R1100) for microbial DNA extraction. Tubes were brought to the clinics immediately or were stored at −20°C for less than 24 hours and then brought to the clinic, where they were stored at −80°C until further processing. DNA was extracted using the DNeasy PowerSoil DNA isolation kit (Qiagen, 12888). Libraries were prepared using standard Illumina tagmentation workflows, and

sequencing was performed on the NovaSeq 6000 platform. Reads underwent quality trimming, host-decontamination, and QC assessment before downstream analysis. Full protocols, reagent lists, and software parameters are provided in the Supplementary Methods.

Microbial taxonomic and functional profiling

Taxonomic profiles were generated using MetaPhlAn v4.1 with the CHOCOPhlAn species genome bin (SGB) database to estimate species-level relative abundances from clade-specific marker genes. The CHOCOPhlAn database leverages systematically organised and annotated microbial genomes and gene family clusters based on the NCBI and UniProt/UniRef reference databases. Functional profiling was performed using HUMAnN v3.9 with default settings. Pathway and taxonomic relative abundances were normalised to enable comparisons across samples. Full database descriptions, software parameters, and filtering criteria are provided in the Supplementary Methods.

Microbial and metabolic pathway differential abundance analyses

Differential abundance analyses were conducted using the R package MaAsLin2 (v1.15.1) at both the species and pathway levels, employing linear regressions adjusted for age, sex, and BMI. Relative abundances were normalised using the centred log-ratio (CLR) method and used as input. Species were included if present in at least one individual in the sample (totalling 1678 species). Additionally, metaCyc pathways were analysed at the species level, as provided by the HuManN pipeline and were included if present in at least one individual (totalling 15,173 species-level metaCyc pathways). Variables demonstrating fewer than two significant associations were omitted.

Colonic pH diversity metrics analysis

Both α and β diversity metrics were calculated based on colonic minimum, median, and maximum pH values, as well as quartile pH data. Specifically, α diversity, which estimates

species diversity within a sample, was calculated using the Shannon and Simpson indices using the microbiome R package. β diversity was calculated at the species level genome bin (SGB) resolution using both unweighted and weighted UniFrac metrics, using the rbiom R package and the Species Genome Bin (SGB) phylogenetic tree version mpa_vJun23_CHOCOPhlAnSGB_202307.nwk provided by MetaPhlAn v4.1.

Statistical analyses

All statistical analyses were conducted in R 4.3.2. Normality was assessed using the Shapiro-Wilk test. To minimise the influence of extreme values, outliers were removed using the interquartile range (IQR) method. For each variable, the first quartile (Q1) and third quartile (Q3) were calculated, and the IQR was defined as the difference between Q3 and Q1. Data points falling below Q1 – 1.5 × IQR or above Q3 + 1.5 × IQR were excluded from further analysis. Comparisons between quartiles were performed using a one-way analysis of variance (ANOVA) followed by pairwise t-tests. Data presented as mean ± standard error of mean (SEM). Spearman's rank correlations were performed on non-normally distributed continuous variables. A significance threshold of $P<0.05$ was used. Adjustments were performed using the Benjamini–Hochberg False FDR method, and $q<0.05$ was considered statistically significant. For alpha diversity, linear regressions (on log-transformed α metrics) were used for continuous variables. For beta diversity, Permutational multivariate analyses of variance (PERMANOVA) using 9,999 permutations were conducted with the adonis2 function from the vegan15 R package.

Acknowledgements

The authors thank Monash University FlowCore, the Monash Statistical Consulting Service, the Monash eResearch capabilities for providing access to M3 servers, and the Australian Genome Research Facility. The authors also thank Dr Matthew Snelson and Michael Nakai for their guided assistance with data analysis tools and experimental work respectively, as well as Dr Meena Madhur and Dr Charles Duncan Smart for their intellectual input and methodological guidance.

Funding

This study was supported by a National Heart Foundation Vanguard Grant (102927) and a National Health & Medical Research Council of Australia (NHMRC) Ideas Grant (GTN2017382). F.Z.M. is supported by a Senior Medical Research Fellowship from the Sylvia and Charles Viertel Charitable Foundation, a National Heart Foundation Future Leader Fellowship (105663), and National Health & Medical Research Council (NHMRC) Emerging Leader Fellowship (GNT2017382). J.A.O. is supported by a NHMRC Fellowship (GNT1124288). S.J.T is supported by NHMRC Ideas Grant (GTN2037610).

Conflict of Interest

None.

Author Contributions

E.D. designed, planned and performed the human immunoprofiling flow cytometry experiment, data analyses, and wrote the manuscript. D.R.J. secured human ethics approval, recruited the participants, and analysed the SmartPill^{TM} data, verified by C.K.Y and D.S.. L.C.T. and C.Y. contributed to analysis tools and data analysis. D.A. and D.C. measured SCFAs. P.R.G. contributed to the interpretation of intestinal pH. C.R.M. contributed towards the central hypothesis and securing funding. J.O.D. provided intellectual input and assisted in

the planning and execution of the human immunoprofiling flow cytometry experiment. J.M. contributed towards trial design, supervision, and data collection and analysis. F.Z.M. conceived and designed the study, secured funding, provided intellectual input and contributed to writing the article. All authors approved of and contributed to the final version of the manuscript.

Data and Code Availability

The codes supporting this study's findings are available at https://github.com/fzmarques/Dinakis-et-al_pH-microbiome-and-immune-system. Microbiome data are available at https://doi.org/10.5281/zenodo.17645792. We did not obtain patient consent for all the data to be made publicly available. However, the data underlying this article can be shared for selected research questions upon reasonable request to the corresponding author. Please email F.Z.M. at francine.marques@monash.edu, who will respond within 4 weeks.

Figures

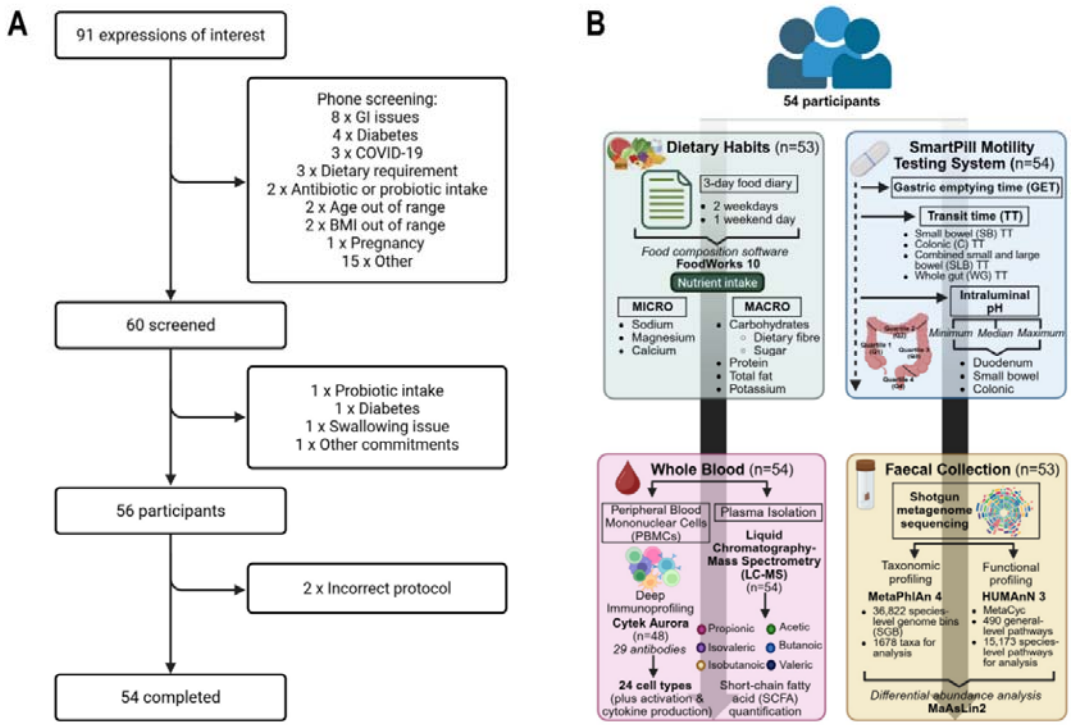

Figure 1

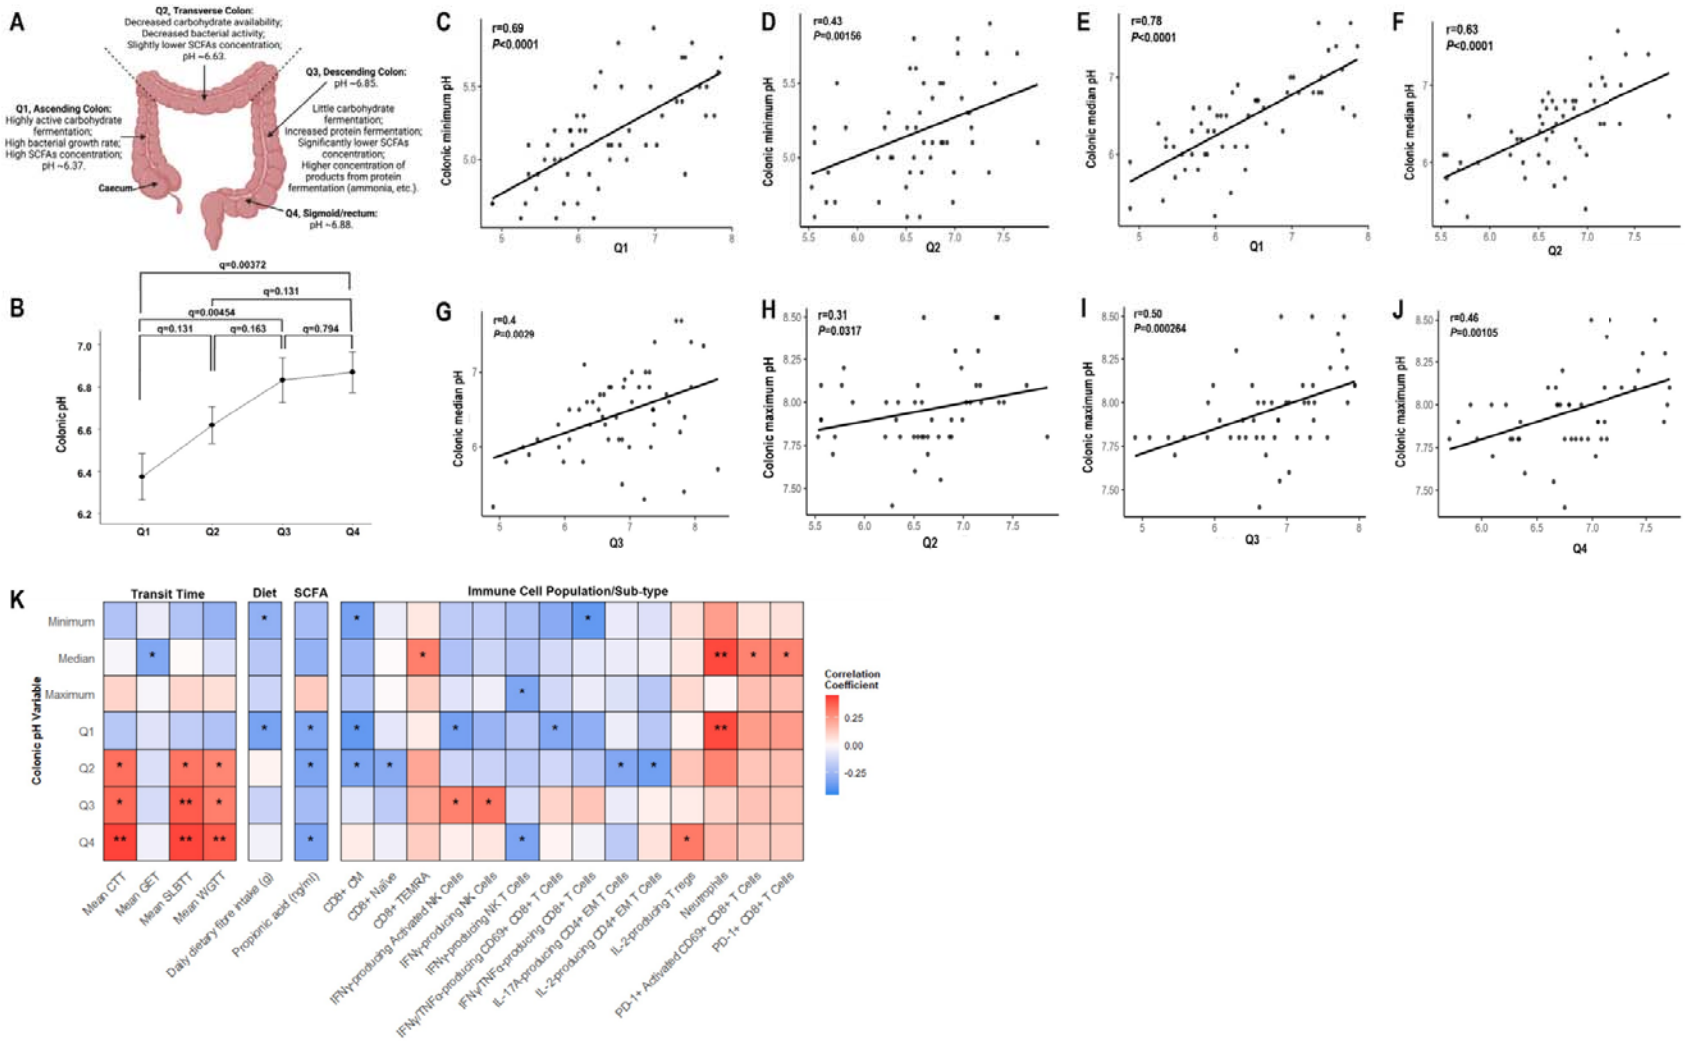
Figure 1. Recruitment and cohort characteristics. (A) Recruitment summary of the pH of Intestines and Blood-pressure Regulation (pHibre) study; out of 91 expressions of interest, 54 participants finished the trial. **(B)** Data collection strategies, methods, and analyses of participants'

dietary habits, SmartPill outcomes, and downstream whole-blood and faecal analyses are summarised. Figures were created on BioRender. GI, gastrointestine; COVID-19, coronavirus disease; BMI, body mass index.



A
Q2, Transverse Colon:
Decreased carbohydrate availability;
Decreased bacterial activity;
Slightly lower SCFAs concentration;
pH ~6.63.
Q3, Descending Colon:
pH ~6.85.
Little carbohydrate fermentation;
Increased protein fermentation;
Significantly lower SCFAs concentration;
Higher concentration of products from protein fermentation (ammonia, etc.).
Q1, Ascending Colon:
Highly active carbohydrate fermentation;
High bacterial growth rate;
High SCFAs concentration;
pH ~6.37.
Caecum
Q4, Sigmoid/rectum:
pH ~6.88.

Figure 2

Figure 2. Colonic pH and associations with immune cells, dietary fibre and short-chain fatty acids (SCFAs). (A) Graphic scheme of the regional pH profile in the colon and respective bacterial activity and SCFA concentration, adapted from[11,97] and created on BioRender. **(B)** Regional pH profile in the colon of the pHibre cohort generated by the SmartPill. **(C-J)** Spearman's rank correlations between colonic minimum, median and maximum pH and quartile data. **(K)** Spearman's rank correlations as heatmaps between colonic pH variables and transit time, diet, plasma SCFAs and immune cell populations/sub-types. Comparisons between quartiles were performed using a one-way analysis of variance (ANOVA) followed by pairwise t-tests. Data presented as mean ± standard error of mean (SEM). Spearman's rank correlations were performed on non-normally distributed continuous variables. The colour gradient represents the strength and direction of correlation (red = positive, blue = negative). Raw unadjusted P-values are presented in heatmaps; *P<0.05, **P<0.01. n=41-54. CTT, colonic transit time; GET, gastrointestinal emptying time; SLBTT, small and large bowel transit time; WGTT, whole gut transit time; SCFA, short-chain fatty acid; CM, central memory; TEMRA, terminally differentiated effector memory T cells; IFN-γ, interferon- γ; NK, natural killer; TNF-α, tumour necrosis factor- α; IL-, interleukin-; EM, effector memory; T regs, T regulatory cells; PD-1, programmed cell death protein 1.

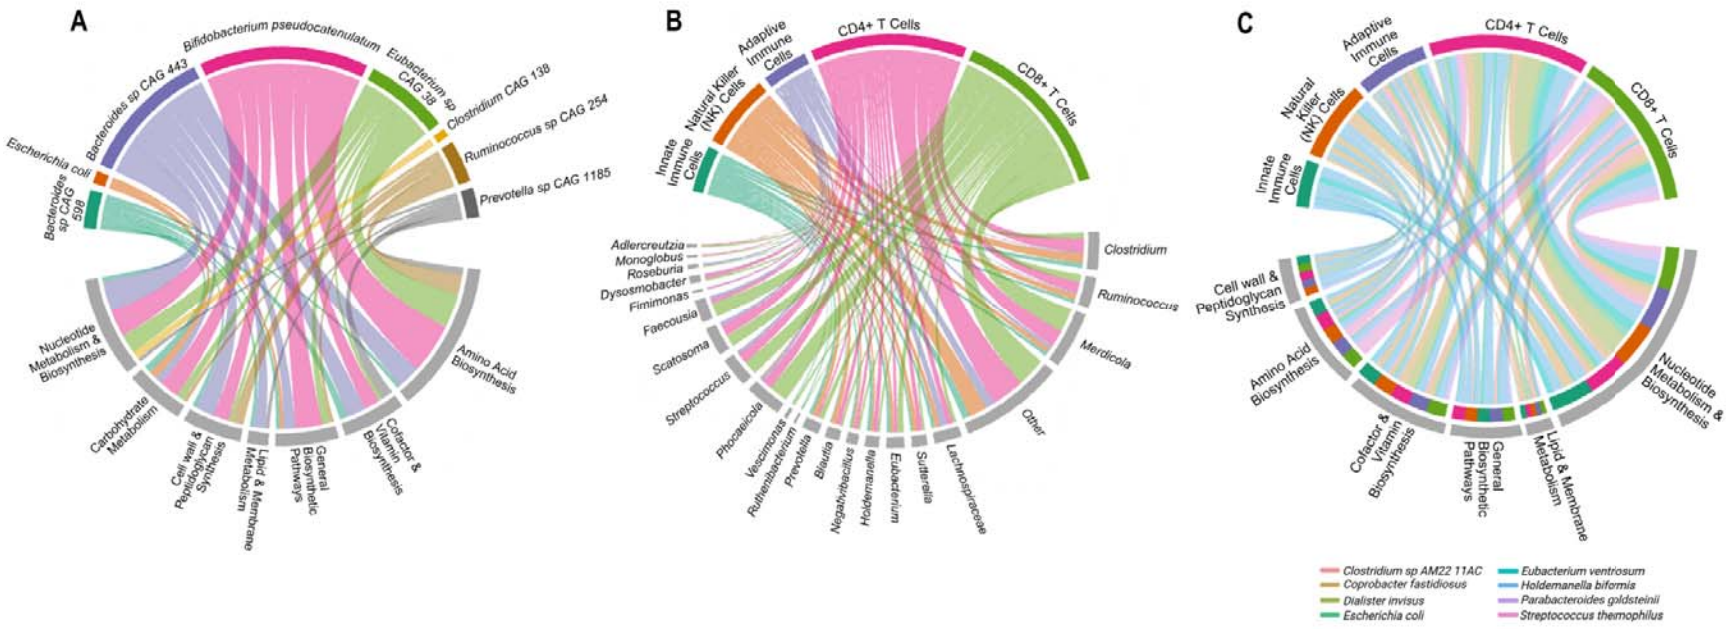

Figure 3

Figure 3. Associations between colonic pH, immune cells, the gut microbiota and species-specific metabolic pathways. Differentially abundant associations between **(A)** colonic pH in the fourth quartile (Q4) and species-specific metabolic pathways (grouped by function), **(B)** immune cell populations/sub-types (grouped into categories) and species (grouped by genus) and **(C)** immune cell populations/sub-types

(grouped into categories) and species-specific metabolic pathways (grouped by function). Differential abundance analyses were conducted using the R package MaAsLin2 (v1.15.1) at both the species and pathway levels, employing linear regressions adjusted for age, sex, and BMI. Relative abundances were normalised using the centred log-ratio (CLR) method. Adjustments were performed using the Benjamini–Hochberg False FDR method. Only significant associations ($q<0.05$) with two or more associations are depicted in the chord diagrams. Line thickness is scaled to the significance of the association ($-\log10(FDR)$). Figures were generated with the circlize R package (v0.4.16). n=48-53.

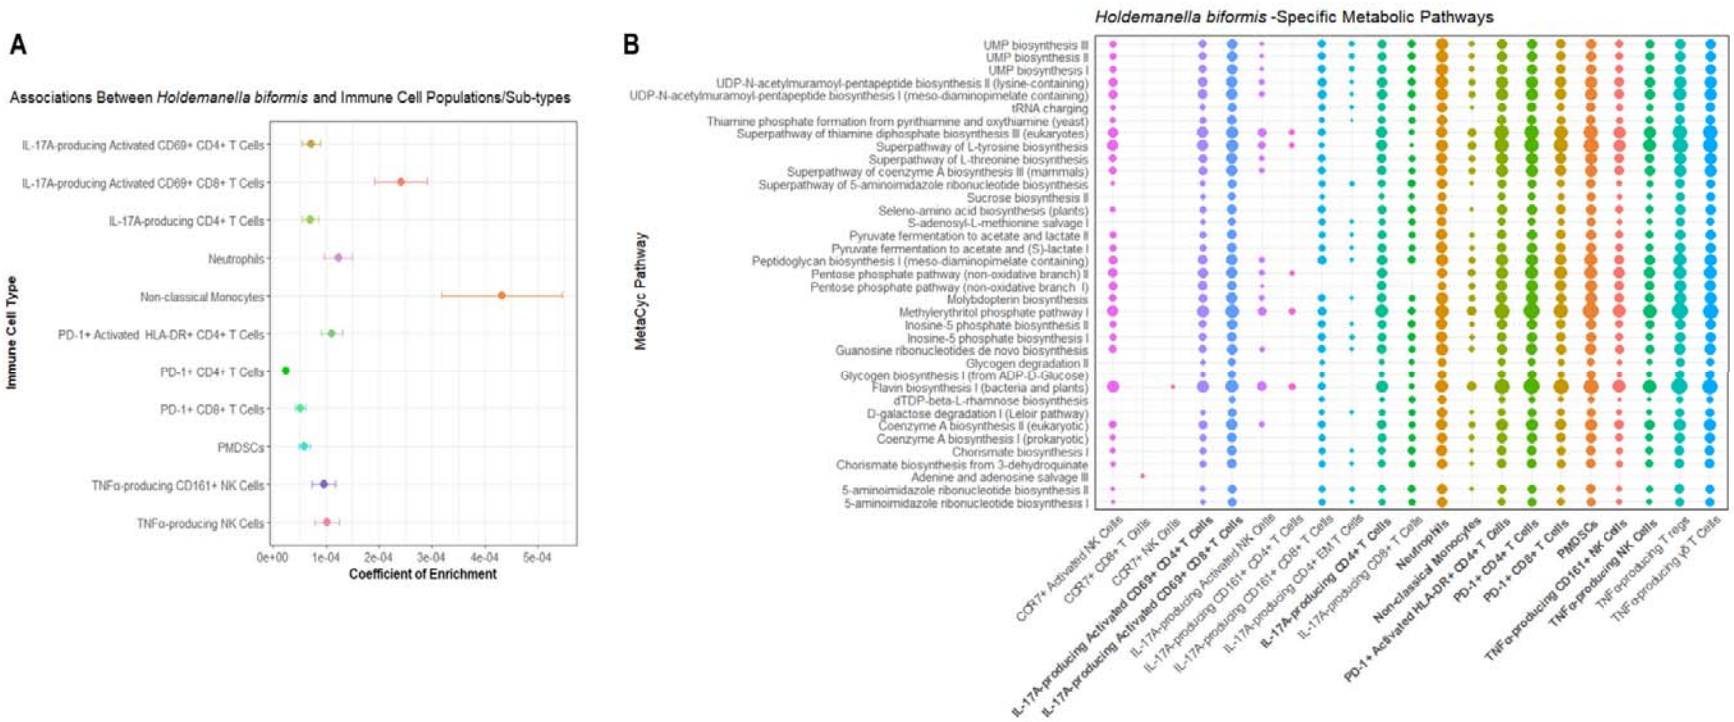

Figure 4

Figure 4. Associations between *Holdemanella biformis* and its pathways with the systemic immune system. Differentially abundant associations between the bacterial species Holdemanella biformis and **(A)** immune cell populations/sub-types, and **(B)** metabolic pathways. Differential abundance analyses were conducted using the R package MaAsLin2 (v1.15.1) at both the species and pathway levels, employing

linear regressions adjusted for age, sex, and BMI. Relative abundances were normalised using the centred log-ratio (CLR) method. Adjustments were performed using the Benjamini–Hochberg False FDR method. Only significant associations ($q<0.05$) are depicted. In panel A, coefficient of enrichment (β) quantifies the direction and strength of the association, with standard errors (SE) shown as horizontal error bars. In panel B, the size of the points corresponds to the significance of the association (−log10(FDR)), and the point colour intensity reflects the scaled effect size (coefficient, β), with stronger colours indicating larger effect sizes. Immune cell types in bold overlap in both analyses. Figures were generated with the ggplot2 R package (v3.5.2). n=48-53. IL-, interleukin-; PD-1, programmed cell death protein 1; HLA-DR, human leukocyte antigen-DR isotype; PMDSCs, polymorphonuclear myeloid-derived suppressor cells; TNF-α, tumour necrosis factor- α; NK, natural killer.

Figure 5

Figure 5. *Eubacterium* species are a key link between the gut microbiota and the systemic immune system. Differentially abundant associations between the bacterial species Eubacterium ventriosum and **(A)** immune cell populations/sub-types, and **(B)** metabolic pathways. Differentially abundant associations between **(C)** quartile 4 (Q4) colonic pH and Eubacterium rectale- and Eubacterium sp CAG 38- specific metabolic pathways. Differential abundance analyses were conducted using the R package MaAsLin2 (v1.15.1) at both the species and pathway levels, employing linear regressions adjusted for age, sex, and BMI. Relative abundances were normalised using the centred log-ratio (CLR) method. Adjustments were performed using the Benjamini–Hochberg False FDR method. Only significant associations ($q<0.05$) are depicted. In panel A, coefficient of enrichment (β) quantifies the direction and strength of the association, with standard errors (SE) shown as horizontal error bars. In panel B, the size of the points corresponds to the significance of the association (−log10 (FDR)), and the point colour intensity reflects the scaled effect size (coefficient, β), with stronger colours indicating larger effect sizes. Immune cell types in bold overlap in both analyses. In panel C, association strength is represented by the weighted –log10(FDR). Figures were generated with the ggplot2 R package (v3.5.2). n=48-53. CCR7, C-C chemokine receptor type 7; CM, central memory; IFN-γ, interferon- γ; T regs, T regulatory cells; IL-, interleukin-; PD-1, programmed cell death protein 1; HLA-DR, human leukocyte antigen-DR isotype; PMDSCs, polymorphonuclear myeloid-derived suppressor cells; TNF-α, tumour necrosis factor- α; NK, natural killer.

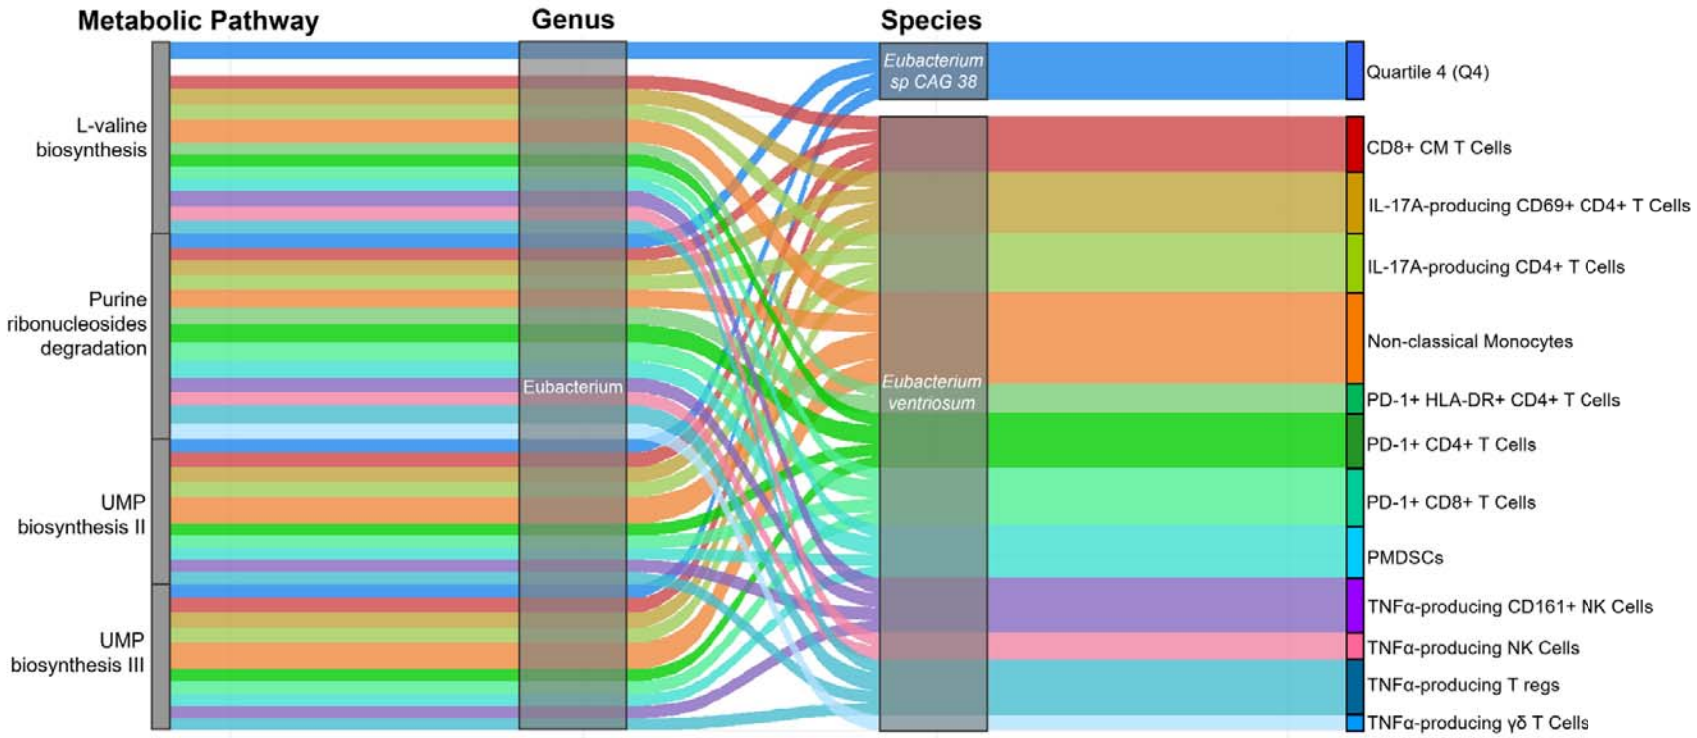

Figure 6

Figure 6. *Eubacterium* species connect microbiota, colonic pH and the systemic immune system. Alluvial diagram showing the connections between significant MetaCyc pathways, bacterial genus and associated species and biological variables, including quartile 4 (Q4) colonic pH and

specific immune cell populations/sub-types. Link widths are weighted by the strength of association (−log10(FDR)). Out of all significant associations detected, these immune cell types, Q4, and metabolic pathways are linked through the Eubacterium genus. Differential abundance analyses were conducted using the R package MaAsLin2 (v1.15.1) at both the species and pathway levels, employing linear regressions adjusted for age, sex, and BMI. Relative abundances were normalised using the centred log-ratio (CLR) method. Adjustments were performed using the Benjamini–Hochberg False FDR method. Only significant associations ($q<0.05$) are depicted. Figure was generated using the ggplot2 (v3.5.2) and ggalluvial (v0.12.5) R packages. n=48-53. CM, central memory; IL-, interleukin-; PD-1, programmed cell death protein 1; HLA-DR, human leukocyte antigen-DR isotype; TNF-α, tumour necrosis factor- α; NK, natural killer; T regs, T regulatory cells.
