Short title: Genetic risk factors for postoperative complications

Abstract (242 words)

Background

Up to 15% of patients worldwide experience serious postoperative complications after major surgery. We explored the genetic basis of five common postoperative complications and whether they share genetic aetiology with their non-postoperative equivalents.

Methods

We performed case-control genome-wide association studies (GWAS) using UK Biobank data from >140,000 participants. The primary outcomes were postoperative acute kidney injury (AKI), atrial fibrillation (AF), myocardial infarction (MI), stroke and surgical site infection (SSI). Additionally, we assessed genetic correlation between UK Biobank postoperative outcomes, as well as between these and their non-postoperative (undifferentiated) equivalents from the FinnGen cohort. Finally, we assessed the association between observed postoperative outcomes and polygenic risk scores (PRS) for their non-postoperative equivalents.

Results

Among 8,472 postoperative complications in 140,563 eligible participants, three genome-wide significant risk loci for AF were identified on chromosomes 1 (*KCNN3*), 4 (*PITX2*) and 16 (*TRAF7:CASKIN1*). No genome-wide significant loci were found for AKI, MI, stroke or SSI. Strong genetic correlation between postoperative and non-postoperative AF was found (r_g = 0.69, p = 0.001). Increasing PRS quintiles for non-postoperative AF, MI, stroke and chronic kidney disease were associated with increased odds of developing the corresponding postoperative complication.

Conclusions

In addition to identifying a novel genomic risk loci associated with postoperative AF, we show that postoperative complications and their non-postoperative equivalents share genetic architecture. These findings suggest that postoperative complications may

represent the acute manifestation of underlying genetic vulnerability, which has implications for preoperative risk stratification and postoperative clinical management.

Introduction

Up to 15% of patients worldwide experience serious postoperative complications after major surgery with significant implications for morbidity, mortality and resource utilisation [1]. These complications represent the interplay between intervention-specific outcomes, the insult of surgery more generally, and underlying vulnerabilities in individuals. They are poorly understood from an aetiological perspective and have few clinically practical predictors to guide preventive treatment.

There is increasing recognition that genetic influences can impact postoperative outcomes and that perioperative care needs to adapt to the era of 'big data' in which 'traditional' risk factors can be combined with individualised data including genomics and other high-dimensional omics [2–4]. Coupled with this is evidence that a seemingly disparate range of postoperative complications may be due, in part, to an aberrant host response to the inflammatory insult of surgery [5–13]. This suggests there could be a common immune-mediated component which is generic rather than organ- or operation-specific.

Genome-wide association studies (GWAS) are a powerful approach to study such complex outcome phenotypes. They can provide insight into the underlying mechanisms and biological substrate whilst identifying genetic variants to be used for risk prediction or therapeutic targeting [14]. GWAS for postoperative complications have examined atrial fibrillation (AF) [15], venous thromboembolism (VTE) [16], acute kidney injury (AKI) [17], and a composite of myocardial infarction (MI), AF, stroke, AKI and delirium [18]. Most have found no associated variants at a genome-wide significance level but sample size has been a common limitation, as has the use of methods which can be unstable in the context of case-control imbalance [19].

To investigate genetic risk factors for postoperative complications and address the methodological limitations of previous studies we conducted a GWAS of postoperative complications after major surgery in the UK Biobank cohort, controlling for case-control imbalance. We focused on AKI, AF, acute MI, stroke and surgical site infection (SSI) as

common, possible immune-mediated complications. We then extended our analyses to explore whether these complications share genetic risk factors with one another, and whether the postoperative phenotypes are genetically related to their non-postoperative equivalents.

Methods

Study populations

The primary analysis was conducted in UK Biobank, a large-scale biomedical database and research resource containing genetic, lifestyle and health information from half a million UK participants recruited between 2006 and 2010 (http://www.ukbiobank.ac.uk). Linked health data is available for all participants with follow-up to 2022 [20]. The UK Biobank study was approved by the North-West Multi-centre Research Ethics Committee and all participants provided written informed consent. This research has been conducted under UK Biobank project number 128619.

FinnGen (freeze 9) was used as an external cohort for genetic correlation analyses. FinnGen is a large-scale genomics initiative that has analysed over 500,000 Finnish biobank samples and correlated genetic variation with health data to understand disease mechanisms and predispositions. The project is a collaboration between research organisations and biobanks within Finland and international industry partners [21].

Genotyping

We used UK Biobank genotype data that was previously generated using Affymetrix using two purpose-designed arrays. The genotype data had been quality controlled, phased and ~96 million genotypes imputed using the Haplotype Reference Consortium and UK10K haplotype resources. FinnGen genotyping used a ThermoFisher Axiom custom chip array with imputation to a reference dataset derived from Finnish whole-genome sequences. Further information on the methods and QC pipeline are available [21,22].

Inclusion and exclusion criteria

We defined eligible participants as those undergoing major, inpatient surgery after their date of enrolment in UK Biobank. Major surgery was defined by OPCS4 codes using the Bupa Schedule of Procedures and Abbott classification [23,24]. Exclusion criteria for all phenotypes included a previous diagnosis of the outcome of interest and planned day case surgery. For acute MI, cardiothoracic and cardiology procedures were excluded to reduce the risk of the diagnosis preceding the procedure (see Supplementary Methods for more detail on phenotype definition and exclusions).

Outcome definition

The primary outcome for each GWAS was a first diagnosis of the complication within a 30 day period following surgery. Controls were defined as those undergoing qualifying surgery but not having the outcome within 30 days. Outcome diagnoses were identified using the following International Classification of Diseases, Tenth Revision (ICD-10) codes: atrial fibrillation, I48.9; acute kidney injury, N17; myocardial infarction, I21; stroke, I61, I63 and I64; and surgical site infection, T81.4.

Genome-wide Association Study (GWAS)

Case-control GWAS adjusted for sex, genetic chip and the first ten genetic principal components was performed for each outcome using REGENIE (v3.2.2) [19]. Previously established MRC-IEU workflows and methods were used for quality control and ancestry definition [25]. Genome-wide significance was defined as $p < 5 \times 10^{-8}$ with an additional exploratory threshold of $p < 1 \times 10^{-6}$. Post-hoc analyses were performed using Functional Mapping and Annotation of Genome-Wide Association Studies (FUMA GWAS [26]). Independent significant SNPs were defined as those meeting the genome-wide significance threshold and independent of each other at a linkage disequilibrium (LD) threshold of $r^2 < 0.6$. Lead SNPs were identified from independent significant SNPs at $r^2 < 0.1$. Gene-based analysis was performed using Multi-marker Analysis of GenoMic Annotation (MAGMA [27]) with a genome-wide significance threshold of $p < 0.05/19{,}840$ (2.52×10^{-6}). For postoperative AF, age was included as an additional covariate [28] and

subgroup analyses were performed after excluding participants who underwent cardiothoracic surgery or cardiology procedures (as defined by treatment specialty).

Genetic correlation analyses between postoperative complications

The GWAS results were used to analyse genetic correlation across phenotypes. Global genetic correlation was assessed through cross-trait LD Score Regression [29,30] and Local Analysis of [co]Variant Association (LAVA) was used to analyse bivariate local genetic correlation in 2,495 predefined regions [31].

Genetic correlation analysis with non-postoperative phenotypes

GWAS summary statistics were obtained from the FinnGen study cohort (Freeze 9, https://r9.finngen.fi/) for non-postoperative equivalents of the outcome phenotypes, i.e. undifferentiated AF, AKI, MI and stroke, as well as chronic kidney disease (CKD). No summary statistics were available for SSI. The results of the primary GWAS analyses were used with this external dataset to analyse global and local genetic correlation between the postoperative and non-postoperative paired phenotypes as above.

Polygenic risk score analysis

Polygenic risk scores (PRS) were identified in the Polygenic Score Catalog (https://www.pgscatalog.org) for non-postoperative AF, AKI/CKD, MI and stroke. No PRS were available for SSI. The *pgsc_calc* workflow [32] was used to download, variant match and calculate individual polygenic scores for the UK Biobank cohort. Scores were included if at least 75% of variants present in the score were also present in the UK Biobank genomic data. Individual scores which passed matching were then centred and scaled before being summed and averaged. The average score was then converted into risk quintiles (1=lowest risk, 5=highest) to improve interpretability [33]. Odds ratios for the association of increasing quintile of PRS for the non-postoperative phenotype with the postoperative equivalent were estimated by logistic regression after adjustment for age and sex using the *glm* function in R (version 4.4.0).

Results

Participant characteristics

A total of 8,472 complications (AF, AKI, MI, SSI, or stroke) occurred in 140,563 eligible individuals. Case-control numbers for each outcome phenotype after excluding previous diagnoses (and cardiothoracic/cardiology procedures for AMI) are shown in Table 1. Most individuals (7,711) had a single complication with 701 and 60 individuals having two and three complications respectively. The most common combinations of complications were AF and AKI (228 individuals) and AKI and SSI (205 individuals).

Individuals who developed postoperative complications tended to be older, were more likely to be male, current or previous smokers and had higher rates of comorbidity (all $p < 0.001$) (Table 2). Compared to controls, cases were more likely to be emergency admissions (2,899 (34%) vs 27,690 (21%), $p < 0.001$) and to have undergone cardiothoracic surgical procedures (1,158 (14%) vs 4,211 (3.2%), $p < 0.001$). Additional details and tables of participant characteristics for each outcome phenotype can be found in supplementary tables 1-6.

Genome-wide association study

A total of 171 genome-wide significant variants were identified for postoperative AF, with nine independent significant SNPs across three genomic risk loci on chromosomes 1, 4 and 16 identified by FUMA GWAS (Figures 1-2; Table 3). The lead SNPs were rs36088503, 4:111697815_TG_T (GRCh37.p13) and rs145672192 respectively. The nearest genes were *KCNN3*, which reached genome-wide significance in a MAGMA gene-level analysis ($p = 2.4 \times 10^{-7}$, Figure 3), *PITX2, RP11-777N19.1* and *TRAF7:CASKIN1*. A further 38 genes were mapped to these regions (supplementary table 7). No genome-wide significant SNPs were found for AKI, AMI, stroke or surgical site infection (supplementary figures 1–8). At an exploratory threshold of $p < 1 \times 10^{-6}$, three independent variants were identified for both AKI and AMI, and eight for SSI (supplementary table 8).

Subgroup analyses were performed for postoperative AF in cardiothoracic and non-cardiothoracic surgery subgroups. No genome-wide significant SNPs or genes were identified for the cardiac surgery cohort (962 cases, 13,504 controls). For the non-cardiac cohort (1777 cases, 122,374 controls), six independent significant SNPs were identified in risk loci on chromosomes 2 and 4 from a total of 162 genome-wide significant variants (supplementary table 9). The lead SNPs were rs12052983 (Chr 2) and rs6843082 (Chr 4). Eighteen mapped genes were identified but none reached genome-wide significance on MAGMA testing.

Genetic correlation between postoperative complications in UK Biobank

No significant global genetic correlation was found between the different postoperative phenotypes in UK Biobank on cross-trait LD Score Regression analysis (supplementary table 10). Local genetic correlation between complications was therefore not assessed given the low SNP-based heritability z-scores and effective sample sizes [29].

Genetic correlation with between postoperative (UK Biobank) and non-postoperative (FinnGen) phenotypes

A strong global genetic correlation was observed between postoperative AF in UK Biobank and non-postoperative AF in the FinnGen cohort (r_g = 0.69, p = 0.001). Significant local correlation was confirmed in two regions near to the *PITX2* (Chr 1) and *KCNN3* (Chr 4) genes identified in the primary GWAS (Table 4). There was some suggestion of shared genetic liability between postoperative AKI and chronic renal failure, but the evidence for global genetic correlation was limited (r_g = 0.42, p = 0.05) and there was little evidence of local genetic correlation. The results for the other phenotypes did not support the presence of global genetic correlation between postoperative and non-postoperative settings (supplementary table 11) and were not analysed further.

Association of polygenic risk scores for related phenotypes (PGS Catalog) with postoperative complications (UK Biobank)

Polygenic risk scores were identified and calculated for non-postoperative AF (20 PRS), AMI (6 PRS) and stroke (25 PRS). No PRS were available for AKI but 20 scores were identified for chronic kidney disease (supplementary table 12). After adjusting for age and sex, increasing PRS quintile was associated with increased odds of postoperative complications for all phenotypes with the most pronounced effects seen for AF and AMI (Figure 4; supplementary table 13). In a subgroup analysis for AF stratified by cardiothoracic/non-cardiothoracic surgery, stronger effects were seen in the non-cardiothoracic cohort: PRS quintile 5, OR (95% CI) for non-cardiothoracic surgery, 6.5 (5.4–7.8), and for cardiothoracic surgery 2.6 (2.1–3.3) (supplementary table 14).

Discussion

In this study we used a UK-based cohort with linked healthcare data to explore the genetic basis of common postoperative complications. We identified three genomic loci associated with postoperative atrial fibrillation (AF) and evidence of shared genetic risk with non-postoperative AF. Similarly, we found common genetic risk factors between postoperative outcomes and their respective non-postoperative counterparts for both myocardial infarction and stroke.

Our study is better powered than previous GWAS of postoperative AF (number of cases/controls: 257/620 and 242/640) which failed to find any genome-wide significant results [34,35]. A comparable previous GWAS of postoperative AF using the UK Biobank cohort reported two variants in proximity to the *PITX2* gene on chromosome 4 [15]. However, our analysis builds on these findings by restricting eligibility to major surgical procedures, defining the outcome phenotype more strictly, and employing a method that is robust in the context of case-control imbalance [19]. We identified independent significant SNPs in a high degree of linkage disequilibrium (LD) with those variants, adding to the evidence implicating the 4q25 locus and *PITX2* gene, established genetic predictors of AF more broadly, in postoperative AF [36–38]. We also found additional risk loci on chromosomes 1 and 16. The 1q21 region has previously been associated with non-postoperative AF in GWAS [38] and post-cardiac surgery AF in a targeted genotyping analysis [37]. We found this region, including the *KCNN3* gene, to be a risk locus for postoperative AF with additional evidence of genetic correlation with non-postoperative AF. The third risk locus identified, 16p13 (lead SNP rs145672192), appears to be a novel finding. It is distinct from an established risk locus for AF more broadly, 16q22 (*ZFHX3*), and is not in LD with this region. The nearest genes are *TRAF7:CASKIN1* which are closely located and coregulated. They may contribute to the development of postoperative AF through roles in inflammatory modulation and signalling (*TRAF7*) or cardiac conduction and excitability (*CASKIN1*).

We found no genome-wide significant variants associated with postoperative AKI, MI, stroke or SSI. Whilst we were better powered than a previous GWAS including AKI, MI

and stroke [35] we were likely only powered to detect large effects. However, our sample sizes for AKI and SSI were similar to that of AF and so it may be that these outcomes are driven more by environmental or direct perioperative factors than underlying genetic susceptibility. This is supported by SNP-based heritability estimates of 22.1% for AF [39] versus <0.1% and 4.5% for AKI after cardiac and non-cardiac surgery respectively [40,41].

The relationship between postoperative and non-postoperative paired phenotypes was explored by genetic correlation and polygenic risk score analyses. Postoperative AF showed the strongest evidence of commonality with its non-postoperative counterpart supported by global, local and PRS-based analyses. The association between increasing PRS and the postoperative outcome was particularly marked in the non-cardiothoracic surgery cohort. Whilst the cardiothoracic cohort was smaller and so relatively underpowered, AF after cardiothoracic surgery has a distinct set of pathophysiological contributory mechanisms which make a reduced genetic influence a plausible finding. No PRS were available for postoperative AKI and so chronic kidney disease was used as the paired phenotype. We found suggestive evidence of global genetic correlation between AKI and CKD as well as increased risk of postoperative AKI with increasing PRS for CKD. Higher PRS quintiles for MI and stroke were also associated with increased risk of the relevant postoperative complication. Taken together, these findings may indicate a 'two-hit' paradigm in which the inflammatory insult of surgery precipitates the outcome in individuals with underlying genetic vulnerability for related chronic pathology.

There may therefore be a role for existing PRS in risk-stratification and preventive perioperative care. In the case of postoperative AF, a review of clinical practice across UK cardiac surgery centres found most did not risk-stratify patients or have a care package in place to prevent postoperative AF [42]. The use of PRS for non-postoperative AF could therefore be a useful adjunct in the pre-operative phase, highlighting those at highest risk who may benefit from a preventive package of care. There are also implications for the longer-term follow-up of acute postoperative complications. Given the presence of shared underlying genetic risk between these postoperative

phenotypes and their non-postoperative equivalents, there will be a proportion of individuals in whom the acute event is the initial presentation of a chronic condition.

This study does have limitations. Some factors which would be of clinical relevance are not collected in UK Biobank or the linked NHS healthcare data, for example ASA physical status grade or type of anaesthesia. Additionally, the UK Biobank cohort is not representative of the wider population, particularly due to differences in socioeconomic status and comorbid status [43]. The postoperative complications studied were defined by clinical coding data and were not prospectively screened for. This may have resulted in some cases being missed; however, this would dilute any observed effect and so suggests our findings are robust to this misclassification. Whilst efforts were taken to minimise the risk of the outcomes preceding surgery it is possible that some cases remain. The limited sample size, particularly for some outcomes, restricted the power of our primary analysis and the application of some genetic correlation methods. Finally, the external cohort used does not define postoperative phenotypes and so direct replication and validation was not possible.

In conclusion, we found multiple genomic risk loci associated with postoperative atrial fibrillation in a major surgery cohort, including a novel locus on chromosome 16 which would benefit from validation and further investigation. We demonstrate evidence of shared genetic aetiology between postoperative complications and their non-postoperative equivalents with implications for both pre-operative risk stratification, through the use of existing polygenic risk scores, and postoperative follow-up, as an acute complication may be indicator or first presentation of an underlying chronic condition.

Tables and figures

Table 1 Numbers of cases and controls for each outcome phenotype in UK Biobank

Outcome	Cases	Controls
Acute kidney injury	3,002	134,941
Atrial fibrillation	2,739	135,878
Surgical site infection	2,701	136,120
Stroke	569	137,842
Acute myocardial infarction	282	123,339

Table 4 Regions of significant local genetic correlation between postoperative atrial fibrillation (in UK Biobank) and non-postoperative atrial fibrillation (in FinnGen)

Chr	Start	Stop	Rho	R^2	p
1	154685546	156813845	0.54 (0.36-0.74)	0.29 (0.13-0.55)	7.3×10^{-8}
4	109978983	111733579	0.58 (0.44-0.73)	0.34 (0.20-0.45)	2.1×10^{-13}

Rho is the estimate of the local genetic correlation between traits (moderate to strong positive correlation: genetic variants in this region may affect both traits in a similar way). R2 is the proportion of variance explained by the local genetic correlation, or how much of the trait variability can be account for by this region. Proportion of covariance between the traits that is explained by variation in this range.
