Running title: makeshift hospital and temperature on mortality of COVID-19

Total words: 1602 words, not including abstract and references

Abstract

Background: In December 2019, a novel coronavirus disease (COVID-19) broke out in Wuhan, China, however, the factors affecting the mortality remain unclear.

Methods: A cross-sectional study based on 32 days (from January 21, 2020 to February 21, 2020) of data that were shared by China National Health Commission and China Weather Net. We compared the difference in the growth rate of confirmed cases and the mortality of confirmed cases and severe cases before and after "Fangcang, Huoshenshan, and Leishenshan" makeshift hospitals (MSHs) were put into use. We also studied whether air temperature (AT) could affect the above outcomes of COVID-19 patients.

Results: Mann-Whitney U test was performed to compare the difference in mortality before and after the use of makeshift hospitals. Eight day after the use of makeshift hospitals, the mortality of confirmed cases was significantly decreased both in Wuhan ($U = 1$, $P < .001$) and Hubei ($U = 0$, $P < .001$), while in non-Hubei regions, as a contrast, the mortality of confirmed cases remained unchanged ($U = 40$, $P = .139$). However, the decrease in the mortality in non-Hubei regions also became significant until sixteen days after the use of makeshift hospitals ($U = 73$, $P = .039$). Mortality of confirmed cases was also found to be significantly correlated with temperature both in Wuhan ($r = .441$, $P = .012$) and Hubei ($r = .440$, $P = .012$) by performing Spearman's analysis.

Conclusions: Our findings indicated that both the use of makeshift hospitals and the rise of temperature were beneficial to the survival of COVID-19 patients. Subsequent studies are suggested to further explore other factors that may affect the mortality of COVID-19, so that this epidemic can be better contained.

Keywords: COVID-19, mortality, makeshift hospitals, air temperature

Introduction

In early December 2019, a novel coronavirus disease (COVID-19, previously known as 2019-nCoV) induced by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) broke out in Wuhan, China.[1,2] This newly discovered coronavirus had been confirmed to have human-to-human transmissibility[3] and has now spread across the country.[4] However, the mortality caused by COVID-19 had been reported to be unbalanced in different regions.[4] Briefly speaking, the mortality in Wuhan city was generally higher than that in other cities, and the mortality in Hubei Province was generally higher than that in other provinces. The specific reason needed to be investigated so that we can better contain the epidemic.

Wuhan as the source of the epidemic, was under great pressure of treatment despite the assistance received from all over the country. Many patients in Wuhan were unable to see a doctor, could not be hospitalized previously. The medical resources consumed by rescuing such patients would then further compress the treatment space of other patients. Such a vicious circle induced by inappropriate resource allocation might be one of the reasons for the high mortality in Wuhan. In addition, by reviewing the outbreak of severe acute respiratory syndrome (SARS) in Guangdong in 2003, we could find that the SARS epidemic gradually subsided with the warming of the weather, and was basically controlled until the warm April and May. Therefore, we assume that different temperatures in different regions might also contributed to the unbalanced mortality.

Up to February 5, 2020, the first three Fangcang, Huoshenshan, and Leishenshan makeshift hospitals (MSHs) had been put into use in Wuhan.[5] The Fangcang hospitals, which belong to field mobile

medical systems, are composed of a number of movable cabins. They have multiple functions such as emergency treatment, surgical disposal, clinical examination and so on. In case of any public health emergency, the cabins can rush to the scene as soon as possible, and then in situ expand to a class II hospital.[6] In the present study, we aim to research whether these MSHs could reduce the mortality induced by COVID-19. In addition, we also studied whether the air temperature (AT) could improve the survival of COVID-19 patients.

Methods

Data collection and mortality calculation

From January 21 to February 21, the number of each day's total confirmed cases, severe cases and new deaths in Wuhan city, Hubei Province and non-Hubei regions were collected by two authors independently. All the above data were available on the official website of National Health Commission of the people's Republic of China (http://www.nhc.gov.cn/). Growth rate of confirmed cases was calculated by dividing the new confirmed cases by the total confirmed cases on the previous day. Each day's mortality was calculated by dividing the number of new deaths by the average number of confirmed cases on that day and the previous day, and mortality of severe patients was calculated by the number of severe cases. Each day's AT were collected from China Weather Net (http://www.weather.com.cn/), and Hubei's AT was represented by that of its capital city (Wuhan). Any inconsistencies were resolved through discussion, or a third author would decide.

Statistical analysis

The data of each region was divided into group A (after the hospitals were built) and group B (before

the hospitals were built). Since the sample size was small (less than 50), the normality of data was

determined using Shapiro–Wilk test, and P value $> .05$ was considered as normally distributed.[7] If the

outcomes of two groups were both normally distributed, Student's t test would be performed to

compare the difference between groups, and if the outcomes of at least one group was skewed

distribution, Mann-Whitney U test would be performed instead.[8] We compared data of eight days,

sixteen days after the use of MSHs, respectively, with the data of sixteen days before the use of MSHs.

As for the correlation analysis, if the AT and the corresponding outcome were both normally distributed,

Pearson correlation analysis would be performed to investigate their correlation, otherwise, Spearman's

correlation analysis would be performed instead.[9] SPSS 26.0 statistical software (IBM, New York,

USA) was used for statistical data processing, and GraphPad Prism 8.3 (GraphPad Software Inc., New

York, USA) was applied for plotting graphs. All tests were two-sided, and P value $< .05$ was

considered as significant.

Results

Mortality difference before and after the use of MSHs

As shown in table 1, for each outcome, at least one group was skew distribution ($P < .05$), so

Mann-Whitney U test was performed to compare the difference between groups. The results eight days

after the use of MSHs are shown in figure 1. The growth rate of confirmed cases was significantly

decreased both in Wuhan ($U = 27$, $P = .023$) and Hubei ($U = 23$, $P = .012$), but in non-Hubei regions,

as a contrast, changes were also significant ($U = 3$, $P < .001$). The mortality of confirmed cases was

significantly decreased both in Wuhan ($U = 1$, $P < .001$) and Hubei ($U = 0$, $P < .001$), while in

non-Hubei regions, as a contrast, the mortality of confirmed cases remained unchanged ($U = 40$, P

= .139). Similarly, the mortality of severe cases was significantly decreased in Hubei ($U = 0$, $P < .001$), while in non-Hubei regions, the change was not significant ($U = 33$, $P = .056$).

Figure 2 shows the results of sixteen days after the use of MSHs. Results of the growth rate of confirmed cases was basically consistent with that of the first eight days. Changes in the mortality of confirmed cases were significant both in Wuhan ($U = 1$, $P < .001$) and Hubei ($U = 0$, $P < .001$), but not like the results of the first eight days, changes in non-Hubei regions became significant ($U = 73$, $P = .038$). Similarly, changes in the mortality of severe cases in Hubei were significant ($U = 0$, $P < .001$), while in non-Hubei regions, changes also became significant ($U = 66$, $P = .019$) this time.

Correlation between AT and outcomes

Except AT, all outcomes were skew distribution as shown in table 2. Therefore, Spearman's analysis was used to investigate their correlation among AT, and the results are shown in figure 3. For the growth rate of confirmed cases, it was not significantly related to AT no matter in Wuhan ($P = .730$) or in Hubei ($P = .062$). But for the mortality of confirmed cases, its correlation between AT was considered to be significant both in Wuhan ($r = .441$, $P = .012$) and Hubei ($r = .440$, $P = .012$). The mortality of severe patients was also found to be significantly related to AT ($r = .421$, $P = .016$).

Discussion

Our study found that after eight days of the use of MSHs, the mortality of COVID-19 patients in Wuhan and Hubei was significantly decreased, while as a contrast, the change in non-Hubei regions was not significant. This preliminarily verified that these MSHs were beneficial to the survival of COVID-19 patients. Later, after another eight days, the difference of mortality between the pre and

post use of MSHs was still significant in Wuhan and Hubei. However, not like the results of the first eight days, the difference in non-Hubei regions became significant. The accumulation of treatment experience of medical staff might be one of the reasons. In addition, according to the trade-off hypothesis, a pathogen must multiply within the host to ensure transmission, while simultaneously maintaining opportunities for transmission by avoiding host morbidity or death.[10] That's to say, coronavirus with weak virulence was more likely to spread than that with strong virulence, which might explain why the mortality in non-Hubei regions also decreased over time. However, empirical evidence remains scarce and the truth needs to be investigated.

Our study also found that the rise of AT could significantly reduce the mortality of both common and severe patients. According to a previous study, the first occurred deaths were mainly elderly people who had comorbidities or surgery history before admission.[11] Acute or chronic cold exposure, however, could elicit bad effects on the respiratory system. Pulmonary mechanics would be compromised by bronchoconstriction, airway congestion, secretions and decreased mucociliary clearance.[12] It has also been reported that cold exposure was coincided with hormonal changes, which might directly or indirectly alter the immune system.[13] The above factors would worsen the underlying medical conditions of elderly people, and this might explain why a warm weather could reduce the mortality of COVID-19 patients.

When it comes to the transmissibility of coronavirus, an *in vitro* study of transmissible gastroenteritis virus and mouse hepatitis virus found that at higher temperatures, these coronaviruses survived for a shorter time on the surfaces of stainless steel.[14] A case-crossover analysis performed in Saudi Arabia also found that primary Middle East Respiratory Syndrome were more likely to occur when condition was relatively cold and dry.[15] However, our results seemed to be inconsistent with these previous

studies, as no significant correlation between AT and the growth rate of confirmed cases in Wuhan was found. One of the potential reasons was that the current AT was not high enough to exert a significant impact on SARS-CoV-2. As the AT gets higher, subsequent studies are necessary to further validate our results. But considering the new cases in tropical areas such as Singapore and Malaysia,[16] it seems that temperature alone would not completely control this epidemic.

Conclusions

The use of MSHs was found to have significantly improved the survival of COVID-19 patients. Although the rise of AT could not directly weaken the infectivity of COVID-19, it could significantly improve the prognosis of patients potentially through ways like improving the respiratory tract.
