ABSTRACT

Objectives: To compare the sound-source localization, discrimination and tracking performance of bilateral cochlear implant users with omnidirectional (OMNI) and pinna-imitating (PI) microphone directionality modes.

Design: Twelve experienced bilateral cochlear implant users participated in the study. Their audio processors were fitted with two different programs featuring either the OMNI or PI mode. Each subject performed static and dynamic sound field spatial hearing tests in the horizontal plane. The static tests consisted of an absolute sound localization test and a minimum audible angle (MAA) test, which was measured at 8 azimuth directions. Dynamic sound tracking ability was evaluated by the subject correctly indicating the direction of a moving stimulus along two circular paths around the subject.

Results: PI mode led to statistically significant sound localization and discrimination improvements. For static sound localization, the greatest benefit was a reduction in the number of front-back confusions. The front-back confusion rate was reduced from 47% with OMNI mode to 35% with PI mode ($p = 0.03$). The ability to discriminate sound sources at the sides was only possible with PI mode. The MAA value for the sides decreased from a 75.5 to a 37.7-degree angle when PI mode was used ($p < 0.001$). Furthermore, a non-significant trend towards an improvement in the ability to track sound sources was observed for both trajectories tested ($p = 0.34$ and $p = 0.27$).

Conclusions: Our results demonstrate that PI mode can lead to improved spatial hearing performance in bilateral cochlear implant users, mainly as a consequence of improved front-back discrimination with PI mode.

23

INTRODUCTION

24 The pinna transforms the spectral characteristics of incoming sound signals dependent on their
25 distance and direction of arrival. The monaural cues resulting from this transformation are particularly
26 important for up-down and front-back localization (Blauert 1997). Cochlear implant (CI) users
27 wearing behind-the-ear audio processors with integrated microphones are not able to utilize pinna
28 cues, which may result in poor localization performance. It has been demonstrated that artificial
29 imitation of the pinna effect in the form of frequency-dependent microphone directionality improves
30 speech intelligibility in noise of CI users when speech and noise are spatially separated (Chung et al.
31 2004; Kordus et al. 2015; Wimmer et al. 2016; Honeder et al. 2018; Dorman et al. 2018). The pinna-
32 imitating (PI) microphone directionality mode available in the Sonnet audio processor (MED-EL
33 GmbH, Innsbruck, Austria), combines the signals of two matched omnidirectional microphones to
34 form a fixed directionality pattern with an increased sensitivity towards the front for frequencies
35 above 2 kHz. The microphones are located in a front/back configuration at the top of the speech
36 processor with a spatial separation of 1 cm. Beamforming is achieved by utilization of phase
37 differences in the arriving sound signal. If only the signal of the front microphone is used, an
38 omnidirectional (OMNI) microphone characteristic is obtained.

39 In contrast to speech intelligibility in noise, only limited data for the localization performance of
40 bilateral cochlear implant (BiCI) users with pinna imitation algorithms are available. Dorman et al.
41 (2018) investigated the influence of a pinna imitation algorithm in BiCI users, concluding no positive
42 effects on sound localization performance. The applied test setup was limited to the frontal azimuth
43 only and did not enable the evaluation of front-back confusions (FBCs). Mantokoudis et al. (2011)
44 placed experimental microphones inside the external auditory canal and measured the minimum
45 audible angle (MAA) of BiCI users. Indeed, sound discrimination at the sides was improved,
46 indicating a potential advantage of pinna cues in BiCI users. This finding is consistent with

47 experiments that showed reduced numbers of FBCs in hearing aid users when applying pinna-
48 imitating microphone directionality (Keidser et al. 2006; Van den Bogaert et al. 2011; Mueller et al.
49 2012; Kuk et al. 2013; Jensen et al. 2013).

50 Another important aspect of spatial hearing performance is the ability to track moving sound sources,
51 especially when realistic test conditions are desired. The ability of BiCI users to perceive and track a
52 virtual moving stimulus in the frontal azimuth has been investigated by Moua et al. (2019). They
53 reported poor performance in discriminating the movement direction and observed overshooting
54 when judging the actual range of sound movements. The experiments used nonindividualized binaural
55 recordings and were limited to the frontal azimuth.

56 To summarize, the spatial hearing of BiCI subjects in general and the influence of the PI directionality
57 in particular remain incompletely understood. Therefore, the aim of this single-blinded study was to
58 investigate the spatial hearing performance of BiCI users in the full azimuthal plane. Since the pinna
59 causes considerable level differences above 2 kHz (pinna shadow) and CI users primarily rely on
60 level cues (Loiselle et al. 2016), we hypothesized that a pinna-effect-imitating microphone setting
61 improves the spatial hearing abilities of BiCI users. As a consequence of the higher sensitivity to
62 sounds arriving from the front, the PI directionality mode should introduce larger changes in ILD
63 magnitude as a function of azimuthal source location, in particular for the front/rear directions. To
64 test our hypothesis, we performed a series of sound field experiments using real sound sources and
65 compared the sound localization, discrimination and tracking abilities of BiCI subjects between the
66 OMNI and PI microphone directionality modes.

68

69

MATERIALS AND METHODS

70 **Study Design and Participants**

71 This prospective study was designed in accordance with the Declaration of Helsinki and was
72 approved by our local institutional review board (Kantonale Ethikkommission-Bern, Switzerland,
73 No. 2018-00901). The study was classified as an observational study according to the Swiss
74 jurisdiction and was deemed to not require registration as a clinical trial. All the participating CI users
75 were postlingually deafened adults even though in four cases the hearing loss was considered to be
76 congenital/progressive. CI01, CI07 and CI12 used hearing aids since early childhood before receiving
77 CIs sequentially. A detailed summary of the participants is provided in Table 1. Only users with
78 monosyllabic word recognition scores in quiet of 70% or better at 60 dB SPL were included in the
79 study. CI users with asymmetries in the number of active electrodes (i.e., more than 1 electrode
80 difference) were not included. This criterion was chosen to increase the homogeneity of the electrode
81 configurations within our study cohort to enable a comparison of results with continuing studies
82 investigating the influence of temporal fine structure preservation on spatial hearing. As a reference,
83 the data of twelve normal-hearing adults were included (Fischer et al. 2019). The participants gave
84 written informed consent before undergoing the study procedure.

85

86 **Audio Processor Fitting**

87 Audio processor fitting was performed in a single-blinded, counterbalanced fashion. All the subjects
88 had at least 4 weeks of experience with their audio processors worn behind both ears before
89 participating in the study. As default setting, the audio processors were programmed with a fine
90 structure preserving sampling coding strategy (FS4) and activated PI directionality mode, which
91 corresponds to the standard fitting used in our clinical routine. Before the study, the audio processors
92 were all set to the same automatic gain control with a compression ratio of 3:1. In addition, the wind

93 noise reduction feature was disabled, and the sensitivity settings were set to the same value for both
94 processors. There was no matching of single electrodes in pitch or volume beyond the clinical routine
95 fitting. According to our counterbalanced study design, half of the subjects started with the
96 microphone directionality set to OMNI, while the other half had an activated PI mode. The subjects
97 were not informed about which settings were activated on their audio processor. Before starting new
98 tests, a trial run was performed for training, the results of which were discarded.

99 **Measurement Setup**

100 The subjects were seated in the center of a horizontal circular loudspeaker setup with a radius of 1.1
101 m inside an acoustic chamber with an approximate reverberation time of 200 ms for frequencies
102 between 0.25 and 10 kHz. The number of loudspeakers (Control 1 Pro, JBL, Northridge, USA) and
103 their positions were adjusted according to the test procedures. To enable real-time dynamic
104 positioning of loudspeakers at different azimuths, we used loudspeakers that were mounted on
105 wireless controllable carriages (see Figure 1) (Fischer et al. 2019). A sound-transparent curtain was
106 used to avoid visual cues during testing. Each loudspeaker was equalized and calibrated with a free-
107 field microphone (type 4133 and preamplifier type 2639, Brüel & Kjaer, Nærum, Denmark) in the
108 center of the circular setup and an audio analyzer (UPV, Rohde & Schwarz, Munich, Germany). The
109 study participants wore eye-tracking glasses during all tests (Pupil Labs, Berlin, Germany) to monitor
110 the head and gaze positions and to minimize orientation-based systematic errors (Razavi et al. 2007).
111 The entire test setup is shown in Figure 1. See supplemental digital content 1 for a video of the setup
112 during an audiometric measurement. A more detailed description of the measurement setup can be
113 found in the article by Fischer et al. (2019).

114

115

116 **Test Procedures**

117 The following test procedures were performed by the study participants with the OMNI and PI
118 microphone directionality modes: (i) static sound-source localization, (ii) MAA assessment for
119 testing sound discrimination, and (iii) sound-source tracking using graphical user interface (GUI)
120 feedback. To minimize bias effects, a counterbalanced study design was used for the microphone
121 directionality modes, the test procedure order and the individual test items. If desired by the subjects,
122 short breaks were taken at any time. The test procedures are described in more detail in the article by
123 Fischer et al. (2019).

124

125 ***Static Sound-Source Localization***

126 We tested the absolute sound localization performance using 12 equally spaced loudspeakers
127 covering the whole azimuthal plane. Three pink noise stimuli with a duration of 200 ms, a 10 ms
128 rise/decay time and a level of 65 dB SPL (roving ± 5 dB) were presented from the loudspeakers in a
129 randomized order (Wimmer et al. 2017; Fischer et al. 2019), resulting in a total of 36 stimuli. The
130 subjects had no prior knowledge about the positions of the loudspeakers, and no feedback was given
131 about the correctness of their answers. They were instructed that stimuli could be presented from any
132 azimuth. Subjects indicated the estimated position using a 1-degree-angle resolution dial-on
133 touchpad. Two seconds after a given response, the next stimulus was presented. Before the test, the
134 subjects could familiarize themselves with the test procedure. The test procedures are described in
135 more detail in the article by Fischer et al. (2019).

136

137 ***Minimum Audible Angle***

138 To investigate the subjects' discrimination abilities, the MAA was measured (Mills 1958) at 8
139 positions, covering the azimuthal plane in 45-degree angle intervals. The MAA is the smallest angular

140 distance that can be detected between the sound sources of two successive tone pulses (Mills 1958).
141 Two tones are played, whereas the second tone is either shifted to the left or to the right regarding the
142 first tone, which stays at the reference position.
143 For each test step, two pink noise stimuli with a duration of 200 ms (10 ms rise/decay time) at a sound
144 pressure level (SPL) of 65 dB were used, separated by a 1-second intrastimulus interval. The
145 perceived stimulus shift was indicated by the subjects using a touchpad showing a GUI, which
146 adapted to the current measurement position. No feedback was given about the correctness of the
147 answers. Before the test, the subjects could familiarize themselves with the test procedure. The test
148 sequence of the azimuthal test positions (i.e., clockwise vs. counterclockwise) was counterbalanced
149 to minimize bias. The first MAA sequence was tested in the frontal direction (0-degree angle). The
150 test procedures are described in more detail in the article by Fischer et al. (2019).

151

152 *Sound-Source Tracking*

153 For sound-source tracking, a continuous pink noise stimulus with a 65-dB SPL was presented from a
154 loudspeaker that was moved with a wireless robotic setup (Fischer et al. 2019). The subjects were
155 instructed to follow the physically moving stimulus by indicating its position on a touchpad. The
156 same GUI as in the static sound-source localization test was used (see the supplementary material of
157 Fischer et al. (2019)). To familiarize the subjects with the task, a trial run was performed, where the
158 position of the stimulus was visible on the GUI. The trajectory of the trial run consisted of a 450-
159 degree angle-spanning trajectory with a single change in direction at the 45-degree azimuth. The
160 maximum angular velocity of the stimulus was 7.4-degree angle per second, which is regarded as
161 suitable for movement detection (Kourosh & Perrott 1990). The test trajectory consisted of a steady
162 trajectory (900-degree angular span, starting at a 315-degree angle with a single change in direction
163 at the 45-degree angle) and an alternating trajectory (2070-degree angular span, starting at a 0-degree

164 angle with 32 changes in direction each at a multiple of 45-degree angle, where each changing
165 position was approached 2 times clockwise and 2 times counterclockwise). The trial and test
166 trajectories are illustrated with video animations in the supplemental material of Fischer et al. (2019).
167 The test procedures are described in more detail in the article by Fischer et al. (2019).

168

169 **Outcome Measures**

170 *Static Sound-Source Localization*

171 The absolute sound localization accuracy was measured with the root mean square error of the static
172 test ($RMSE_{LOC}$, in degree angle) averaged over the total number of stimuli ($N = 36$) (Hartmann 1983).
173 For a direction-specific analysis, the $RMSE_{LOC}$ was calculated over the 3 stimuli given from a
174 particular direction. To evaluate the influence of possible FBCs on the performance (Letowski &
175 Letowski 2011), the localization accuracy was also evaluated under the exclusion of responses that
176 crossed the interaural axis with respect to the loudspeaker providing the stimulus. Responses with
177 this pattern are referred to in the literature as FBCs (Rayleigh 1907). The chance levels for the overall
178 localization error ($RMSE_{LOC}$) are 104 ± 8 -degree angle (including FBCs) and 79 ± 10 -degree angle
179 (excluding FBCs). To further quantify the FBCs, the FBC rate, which is defined as the number of
180 FBCs divided by the number of stimuli presented, was computed. The chance level of the FBC rate
181 for the measurement setup used in this study was $50\% \pm 9\%$.

182

183 *Minimum Audible Angle*

184 We measured the MAA with a two-alternative forced-choice procedure with a 2-down, 1-up rule.
185 Each MAA in a specific direction was measured using 24 steps, determined by an updated maximum
186 likelihood estimation procedure (Shen et al. 2015). The number of steps was determined from pilot
187 tests before the study to ensure the convergence of the MAA. The starting step size of 15-degree

188 angle, a logistic-shaped psychometric function and the parameter range of the angular displacement
189 from 0.5-degree angle to 90-degree angle further characterized the procedure. The MAA for each
190 position was defined as the corresponding 80%-correct threshold of the estimated psychometric
191 function (Senn et al. 2005). The chance level of our MAA test procedure for a specific direction was
192 83 ± 15 -degree angle (24-step sequence with a starting step size of 15-degree angle and maximum
193 likelihood step size adaptation).

194

195 *Sound-Source Tracking*

196 Analogous to the static source localization test, the root mean square error (RMSE) was assessed for
197 every sampled position of the stimulus. We refer to the dynamic position-tracking error as $RMSE_{\theta}$ (in
198 degree angle). In addition, the percentage of correctly indicated directions of stimulus movement
199 (clockwise or counterclockwise) was recorded. The error between the indicated and actual stimulus
200 angular velocities was calculated as the $RMSE_{\omega}$ (in degree angle per second). To evaluate whether
201 the subjects lost track of the stimulus, we defined events with high indicated velocities (i.e., greater
202 than 3 times the stimulus velocity) as a relocalization of source (ROS). The occurrence of ROS events
203 (N_{ROS}), their duration Δt_{ROS} (ms) and the improvement in the tracking error after a ROS event
204 ($\Delta RMSE_{\theta, ROS}$ in degree angle) were recorded. A detailed description of the metrics is provided in the
205 article by Fischer et al. (2019).

206

207 *Statistical Analysis*

208 Descriptive statistics were used to compare the performance of the subjects on the group level. The
209 effects of the different microphone directionality modes (PI vs. OMNI) were compared using two-
210 sided Wilcoxon signed-rank tests. On the subject level, a correlation analysis was performed by
211 means of Pearson correlation coefficients to assess the relation between the outcome measures and

212 the years of CI experience, word recognition scores, and age of the subjects. The chance levels for
213 the used test procedures were estimated using Monte Carlo simulations. Statistical calculations were
214 performed in MATLAB (version R2018a, The MathWorks Inc., USA).

215

RESULTS

216

217 **Static Sound-Source Localization**

218 Figure 2 shows the absolute localization accuracy for each stimulus direction for the OMNI and PI
219 modes (see supplemental digital content 2, Figures 1 and 2 for confusion matrices). Under the
220 exclusion of the FBCs, the localization performance in OMNI mode was the worst in the rear azimuth
221 at 150-, 180- and 210-degree angles with $RMSE_{LOC}$ values of 42 ± 18 -degree angle, 41 ± 27 -degree
222 angle and 44 ± 27 -degree angle, respectively. The best localization performance was observed at a
223 120-degree angle and a 240-degree angle with 17 ± 9 -degree angle and 15 ± 9 -degree angle,
224 respectively. In PI mode, the localization errors at the rear azimuths (150, 180 and 210-degree angles)
225 were reduced, leading to a similar performance compared to the frontal azimuths (330, 0 and 30-
226 degree angles). Analogous to the results in OMNI mode, the best localization performance was
227 observed at a 120-degree angle and a 240-degree angle (12 ± 8 -degree angle and 13 ± 9 -degree angle,
228 respectively).

229 Including the FBCs, for both microphone modes, the lowest $RMSE_{LOC}$ values were observed at a 90-
230 degree and a 270-degree azimuth. Since the FBCs are undefined at these azimuths and do not
231 contribute to the error measure, this finding may not indicate good localization performance, but
232 rather shows the dominance of the FBC related errors. The largest impact of the FBCs on the
233 $RMSE_{LOC}$ was measured at a 180-degree azimuth. See supplemental digital content 2, Tables 1-4 for
234 a detailed summary of the results.

235 The $RMSE_{LOC}$ over all directions with FBCs included was significantly lower in PI mode than in
236 OMNI mode (reduction from 65 ± 7 -degree angle to 52 ± 13 -degree angle, $p = 0.007$). For comparison,
237 normal-hearing subjects achieved an $RMSE_{LOC}$ of 13 ± 4 -degree angle in the identical test procedure
238 (Fischer et al. 2019). Without the FBCs, the improvement in PI mode compared to OMNI mode was

239 not statistically significant (28 ± 6 -degree angle to 31 ± 7 -degree angle, $p = 0.29$).

240 The FBC rate improved from 47% (OMNI) to 35% (PI) with $p = 0.03$. As a reference, normal-hearing
241 subjects had an FBC rate of 4%. A separate analysis between front-back and back-front confusions
242 did not show a preference of the PI mode to reduce either front-back or back-front confusions (see
243 supplemental digital content 2, Tables 5 and 6). Of the 12 subjects, 8 had lower FBC rates with the
244 PI mode than with the OMNI mode.

245 **Minimum Audible Angle**

246 The MAA results for the OMNI and PI modes averaged across all subjects are shown in Figure 3. In
247 both modes, the MAA was best at the front at 0-degree angle and the back at 180-degree angle. The
248 worst performance was measured at the sides at 90 and 270-degree angle. At the sides, where the
249 MAA is equivalent to a front/back discrimination task, a significant improvement from 75.5 ± 23.0 -
250 degree angle in OMNI mode to 37.7 ± 21.3 degrees in PI mode ($p < 0.001$) was measured. Furthermore,
251 the MAA averaged across all the measurement directions improved significantly from 30.3 ± 7.6
252 degrees to 20.8 ± 6.6 -degree angle when PI mode was used ($p = 0.003$). For comparison, normal-
253 hearing subjects achieved an averaged MAA of 3.6 ± 1.6 -degree angle (Fischer et al. 2019). See
254 supplemental digital content 2, Tables 7 and 8 for individual MAA results with the OMNI and PI
255 modes. Using the OMNI mode, 7 subjects were better than the chance level at the 90-degree angle
256 and the 270-degree angle measurement positions. Two subjects were close to the chance level at the
257 sides. In PI mode, 10 subjects were better than the chance levels. The 2 subjects that did not perform
258 better than the chance level in PI mode, exceeded it for either the 90-degree angle position or for the
259 270-degree angle position. For both modes, the MAA was significantly smaller for the frontal
260 azimuths (315, 0 and 45-degree angles) than for the rear azimuths (135, 180 and 225-degree angles)
261 (OMNI $p < 0.001$ and PI $p = 0.01$). This could not be observed for the left (225, 270 and 315-degree

262 angles) and right azimuths (45, 90 and 135-degree angles) (OMNI $p = 0.68$ and PI $p = 0.43$). Similar
263 to the absolute localization performance, the correlation analysis did not reveal any statistically
264 significant relations.

265 **Sound-Source Tracking**

266 *Steady Trajectory*

267 The subjects had slightly better sound-source tracking abilities with PI mode compared to the
268 performance with OMNI mode. The tracking error $RMSE_{\theta}$ and velocity-tracking error $RMSE_{\omega}$ were
269 nonsignificantly reduced from 62.3 ± 12.7 -degree angle to 55.6 ± 20.9 -degree angle ($p = 0.34$) and from
270 3.2 ± 1.1 -degree angle per second to 2.6 ± 1.1 -degree angle per second ($p = 0.20$), respectively. The
271 proportion of correctly indicated movement directions throughout the experiments improved
272 nonsignificantly from 64% to 74% ($p = 0.08$). In OMNI mode, 4 subjects did not perceive the single
273 change in direction, and 1 subject indicated a movement in the counterclockwise direction only. This
274 finding was also the case in the PI mode, where 5 subjects did not perceive the change in direction, 2
275 of them showing an identical tracking behavior as in OMNI mode. It is noticeable that the subjects
276 often used the passages at 0-degree angle or 180-degree angle as the orientation instead of the change
277 in direction (see supplemental digital content 2, Figure 5 for an illustration). For the individual
278 tracking results and outcome measures of the subjects, please see supplemental digital content 2,
279 Tables 9 and 10.

280

281 *Alternating Trajectory*

282 Figure 4 shows the physical sound-source positions, the positions indicated by the subjects and the
283 resulting tracking errors during the alternating-trajectory experiments. The tracking error $RMSE_{\theta}$ of
284 the subjects was nonsignificantly reduced from 67-degree angle in PI mode to 61-degree angle ($p =$

285 0.27) in OMNI mode (see Table 2). As a reference, the normal-hearing subjects achieved an $RMSE_{\theta}$
286 of 19-degree angle in the same experiment (Fischer et al. 2019). On the subject level, 8 subjects
287 achieved a lower $RMSE_{\theta}$ with PI mode. For the remaining metrics, the tracking results were similar
288 for both microphone modes. See supplemental digital content 2, Tables 11 and 12 for a detailed
289 summary of the outcome metrics at the subject level.

290 Compared to the normal-hearing subjects, BiCI users had great difficulty reacting to changes in
291 direction. Similar to the steady-trajectory experiment, the 0-degree angle and 180-degree angle
292 passages of the sound source were used for orientation. This difficulty was especially visible in OMNI
293 mode, resulting in tracking plateaus when the sound source was in the proximity of the interaural axis
294 (see Figure 4). The movement direction of the sound source (clockwise vs. counterclockwise) did not
295 have an effect on the tracking error $RMSE_{\theta}$.

296 With both microphone modes, the subjects had a lower position-tracking error ($RMSE_{\theta}$) in the frontal
297 hemisphere than in the rear hemisphere. This difference was statistically significant in PI mode
298 (66 ± 24 -degree angle in the back vs. 53 ± 18 -degree angle in the front; $p = 0.02$). In OMNI mode, a
299 smaller nonsignificant difference was observed (67 ± 21 -degree angle in the back vs. 63 ± 20 -degree
300 angle in the front; $p = 0.60$). For comparison, normal-hearing subjects showed a better tracking
301 performance in the front (16 ± 4 -degree angle) compared to the back (21 ± 6 -degree angle, $p = 0.005$),
302 similar to that in PI mode (Fischer et al. 2019). See supplemental digital content 2, Tables 13 and 14
303 for additional data of the hemifield and movement direction-related analyses. Only in PI mode did
304 the static localization error $RMSE_{LOC}$ correlate significantly with the corresponding position-tracking
305 error $RMSE_{\theta}$ of the alternating trajectory ($p = 0.03$). See supplemental digital content 2, Figure 7 for
306 the scatter plot. Otherwise, the correlation analysis showed no statistically significant correlations in
307 the tracking experiments.

308

DISCUSSION

309 Herein, we present a comprehensive analysis of the sound localization, discrimination and tracking
310 performance of the BiCI users. Our main finding is that the PI microphone directionality mode
311 enables better differentiation between acoustic cues from the front and the back. With PI mode
312 enabled, the BiCI users benefited from the monaural cues provided by the direction-dependent
313 frequency shaping of the pinna-imitating microphone setting (Blauert 1997). As a consequence, the
314 spatial hearing abilities of the participants assessed in terms of sound localization, discrimination and
315 tracking were better when using PI mode than OMNI mode.

316 A critical examination of the study results or design could raise the question of whether the measured
317 effects were significantly influenced by the different acclimatization periods of the BiCI users
318 between the PI and OMNI settings. However, compared to the experiments performed by Hofman et
319 al. (1998) and Van Wanrooij & Van Opstal (2005), we did not apply a spectral perturbation of the
320 pinna but completely eliminated its influence by applying the OMNI setting, which implied that very
321 little monaural information was available that could have been learned (Opstal 2016). Since our main
322 outcome in this study was to show the ability of PI mode to resolve acoustic ambiguities due to the
323 cone of confusion, we hypothesize that a longer acclimatization period would not significantly alter
324 the measured effect.

325

326 **Static Sound-Source Localization**

327 The most obvious influence of PI mode on static sound-source localization is the reduction in the
328 occurrences of FBCs. This reduction resulted in a statistically significant improvement in the overall
329 sound localization error $RMSE_{LOC}$ compared to OMNI mode. Only limited data are available for tests
330 performed with BiCI users in the full horizontal plane, which is required for an analysis of FBCs.

331 Compared to the study by Pastore et al. (2018), who did not specify a microphone directionality
332 setting and used a setup with coarse angular spacing (60-degree angle) with 3 seconds of stimuli, our
333 observed FBC rates were 7% lower in PI mode and 5% higher in OMNI mode. In contrast to Pastore
334 et al. (2018), the majority of confusions that we observed were not back-to-front confusions. The
335 study by Frohne-Büchner et al. (2004) reported a significant improvement in the localization
336 performance with an in-the-canal microphone for unilateral CI users. However, an FBC analysis was
337 not performed, although they most likely caused the significance in the $RMSE_{LOC}$ differences. Majdak
338 et al. (2011) tested spatial hearing performance with virtual cues presented via the auxiliary inputs of
339 the audio processors and reported an FBC rate of 37%, which was 2% higher than our results with
340 the PI setting. In contrast to this study, the patients received visual feedback after indicating the
341 perceived sound location.

342 For the frontal azimuth, our results are comparable to the data of Dorman et al. (2018) and Jones et
343 al. (2016), who reported an $RMSE_{LOC}$ of 19-degree angle and 25-degree angle for OMNI mode,
344 respectively. For PI mode, $RMSE_{LOC}$ values of 20-degree angle and 29-degree angle were reported,
345 respectively. In our setting, an $RMSE_{LOC}$ of 27-degree angle for OMNI mode and 23-degree angle for
346 PI mode for the frontal azimuth was observed. On average, no significant differences in the
347 localization performance between the OMNI and PI modes were observed for the frontal hemisphere
348 in our study.

349 Independent of the microphone setting and including the FBCs in the error calculations, the highest
350 averaged errors for the BiCI users occurred in the very frontal and back azimuths and were rather
351 small at the lateral azimuths. This finding is in line with the available interaural time difference (ITD)
352 and, in particular, ILD cues, which are most prominent at the lateral azimuth. A similar pattern was
353 observed in the study by Majdak et al. (2011). In line with the azimuth-dependent intensities of the
354 binaural cues, the histograms (see supplemental digital content 2, Figures 3 and 4) show that for both

355 microphone settings, the BiCI users tended to perceive the direction more at the sides than at the front
356 or the back. From a statistical point of view, such a response distribution favors the small errors we
357 measured at the sides. In contrast to the findings of Nopp et al. (2004) and Majdak et al. (2011), on
358 average, our study participants had no preference for perceiving stimuli at the left or right azimuth.
359 Additionally, no preference for the frontal versus rear azimuth was observed, regardless of the
360 microphone setting. For this comparison, we excluded the 0-degree angle and the 180-degree angle
361 for the sides' analysis and the 90-degree angle and the 270-degree angle for the front versus rear
362 analysis. See supplemental digital content 2, Table 16 for a comparison of the data from this study
363 with the references mentioned in this section.

364

365 **Minimum Audible Angle**

366 We present an MAA profile of BiCI users for a full azimuth configuration at 8 different directions up
367 to the theoretical measurement limit of ± 90 -degree angle. Previous studies investigating the MAA of
368 BiCI users were restricted to a maximum displacement between the sound sources of 45-degree
369 angles and thus could not measure the MAA at the sides (Senn et al. 2005; Mantokoudis et al. 2011).
370 To the best of our knowledge, this is the first study to cover MAA values at the sides (i.e., at a 90-
371 degree angle and a 270-degree angle) in BiCI users. With OMNI mode, the majority of our
372 participants had MAAs at the left and right sides that by far exceeded 45-degree angle, which was
373 also observed by Senn et al. (2005) and Mantokoudis et al. (2011). As hypothesized by Senn et al.
374 (2005), the spatial discrimination at the sides was substantially reduced in PI mode. In the study by
375 Mantokoudis et al. (2011), experimental microphones were placed inside the ear canal, demonstrating
376 a theoretical benefit of pinna cues for the sound discrimination of BiCI users at the sides. As our setup
377 was not limited to a maximum MAA of 45-degree angle, we were able to quantitatively show this

378 effect and reproduce the results of Mantokoudis et al. (2011) in a more refined setting.

379 Since there are no ITD or ILD cues for MAA measurements at the sides, the MAA measurement
380 equals a front/back discrimination task at the 90 and 270 degree angle positions. Similar to the static
381 sound localization tests, the impact of PI mode on the localization or discrimination performance was
382 highest when resolving ambiguities from the cone of confusion. However, we could not observe
383 statistically significant correlations at the subject level between the FBCs in the static sound
384 localization test and the performance of the MAA at the sides with either microphone mode.

385 We were further unable to confirm the relationship between the MAA at a 0-degree angle and frontal
386 sound-source localization accuracy found by Grieco-Calub & Litovsky (2010) for children using
387 BiCI. In contrast to Senn et al. (2005), we observed statistically significant differences between the
388 frontal quadrants (i.e., at a 45-degree angle and a 315-degree angle, $p = 0.01$) and rear quadrants (i.e.,
389 at a 135-degree angle and a 225-degree angle, $p < 0.001$) with both settings. The results for the frontal
390 quadrants were in the range of the results reported by Senn et al. (2005); however, for the rear
391 quadrants, we observed larger MAAs. The difference in performance between the left and right sides
392 was not obvious in our static localization test (i.e., localization errors at 300, 330, 30, 60-degree angles
393 versus at 120, 150, 210, 240-degree angles). For the positions in the front and the back (0 and 180-
394 degree angles, respectively), we could confirm the values of Senn et al. (2005) but report slightly
395 higher values for the back position and OMNI mode due to the high MAA values of 3 subjects. See
396 supplemental digital content 2, Table 15 for a comparison of the data from this study with the
397 references mentioned in this section.

398

399 **Sound Source Tracking**

400 The BiCI users had an overall improved sound-source tracking performance with PI mode compared

401 to the OMNI mode; however, the differences in the outcome measures were not statistically
402 significant. The main findings for the alternating- and steady-trajectory experiments are identical
403 regarding the performance of the BiCI users. The continuous movement of the steady trajectory did
404 not provide a reliable sound tracking cue for the BiCI users. Although the tracking error $RMSE_{\theta}$ was
405 lower in PI mode than in OMNI mode, the variability between the subjects was higher in PI mode.
406 Compared to our normal-hearing control subjects, the tracking error $RMSE_{\theta}$ of the BiCI users was 4
407 times larger in PI mode (Fischer et al. 2019).

408 The analysis of the tracking errors using the FBC rate showed a statistically significant lower rate
409 with PI mode ($33\% \pm 16\%$) than with OMNI mode ($46\% \pm 15\%$, $p = 0.02$). Because the steady trajectory
410 contained no changes in the movement direction of the stimulus at the interaural axis, this effect was
411 only significant for the alternating trajectory. Evaluated in the dynamic setting, FBCs indeed occur
412 more often if pinna-cues were absent. This finding is novel for BiCI users, and we hypothesize that
413 it is a consequence of the high MAA values at the sides. The very frontal (0-degree angle) and
414 backward (180-degree angle) directions seem to be important landmarks for dynamic auditory
415 perception, which can be seen in the "plateau" tracking in OMNI mode (see Figure 4, left side).

416 For both of the tested trajectories, the difference in ILD cues had to be evaluated to make an
417 assumption about the shift in the sound source. As the changes in the ILD intensities at the sides are
418 particularly small, we hypothesize that in addition to the cone of confusion, this difference affected
419 the discrimination abilities at the sides. In addition, we observed intense relocalization reactions to
420 the indication of the stimulus position whenever the stimulus passed the sagittal plane, where the
421 difference in ILD cues was at a maximum. On the other hand, we observed a moderate correlation
422 between the $RMSE_{LOC}$, which evaluates absolute ILD cues rather than the differences, and the $RMSE_{\theta}$
423 in the alternating trajectory (see supplemental digital content 2, Figure 7 for the scatter plot).
424 Therefore, not only relative but also absolute localization cues may be of importance for the sound

425 tracking abilities of BiCI users.

426 Since studies on the continuous tracking ability of BiCI users with regard to a moving stimulus were
427 sparse, a comparison with the literature was only possible to a limited extent. Studies with moving
428 sounds and BiCI users have been performed by Moua et al. (2019) at the frontal azimuth. However,
429 feedback was always provided after the moving stimulus was presented via nonindividualized
430 binaural recordings. Nevertheless, in the study by Moua et al. (2019), as in this study, substantial
431 differences were found in the perception of moving sound sources between BiCI and normal-hearing
432 (NH) subjects. For the alternating trajectories, we observed that BiCI users performed near the chance
433 level of 50% concerning the indication of the correct movement direction. In contrast, normal-hearing
434 subjects achieved a score of 83% (evaluated by Fischer et al. (2019)). For the steady trajectory, a
435 similar pattern was observed with an average performance of 70% correct for the BiCI users and 97%
436 correct for the normal-hearing subjects. The tracking error $RMSE_{\theta}$ in both trajectories were 3-4 times
437 higher for the BiCI users than for the NH subjects. The continuous presentation of a slowly moving
438 stimulus did not provide a reliable auditory cue for tracking the motion. In addition to sudden changes
439 in the perceived moving direction of the stimulus, it was observed that almost half of the BiCI users,
440 with 2 subjects overlapping in both settings, were not able to detect the only change in direction
441 appearing at a 45-degree angle during the steady-trajectory test. Analyzing the subjects who perceived
442 the change in direction in PI mode and in OMNI mode did not show a significant difference in the
443 perception in terms of reaction times.

444 As BiCI users almost entirely rely on ILD cues for sound localization in the azimuthal plane (Aronoff
445 et al. (2010)), automatic gain-control settings of the audio processors might play an important role in
446 auditory motion perception. Archer-Boyd & Carlyon (2019) investigated this effect using head
447 movements of a head-and-torso simulator. With the investigated system (Advanced Bionics Ltd.,
448 Valencia, CA), they reported that the ILDs received by the BiCI were distorted due to auditory motion

449 induced by head movements. The system used in our study has 4 times smaller compression ratios
450 compared to the devices tested by Archer-Boyd & Carlyon (2019). Nevertheless, automatic gain-
451 control could have caused the limited sound-source tracking performance of the BiCI users. Further
452 investigations with dynamic sound-source positions need to be performed to evaluate this effect.

453 Because CI processors are not synchronized, different peaks might be picked up by the audio
454 processors, leading to a nonsmooth or erroneous representation of the auditory motion image (Kan et
455 al. 2018). However, as stated above, we believe that automatic gain-control settings, which distort
456 the perception of dynamic ILDs, play a more important role in the perception of auditory motion for
457 BiCI users. We observed that a pinna-imitating microphone setting may help to mitigate distorted
458 ILDs by adding localization cues due to the spectral filtering of incoming sounds.

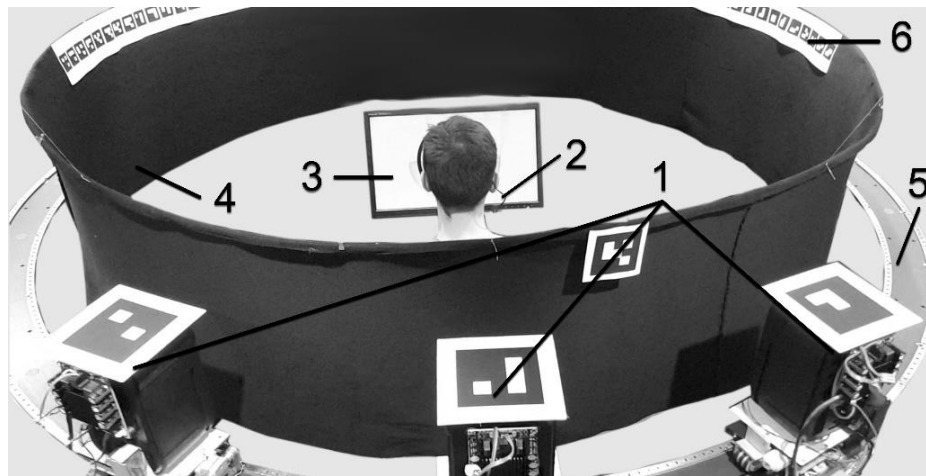

459

460 **Conclusions**

461 In this study, we showed the benefits of pinna-imitating (PI) microphone directionality for the spatial
462 hearing abilities of BiCI users tested under sound field conditions in the horizontal plane. Our results
463 suggest that the PI mode facilitates auditory spatial perception in everyday listening scenarios for
464 BiCI users. Regardless of the microphone setting, BiCI users showed great difficulty in tracking a
465 moving sound source compared to the NH subjects. Furthermore, we hypothesize that the effect of
466 distorted ILD cues due to the automatic gain-control setting could have had an impact on the tracking
467 performance.

472 180-degree azimuth. Three wireless controllable audio robots with optical tracking markers (1), eye-
473 tracking glasses (2), a touch screen with a graphical user interface (GUI) (3), sound-transparent
474 curtain (4), a low-noise rail (5) and azimuth reference markers (6).

475

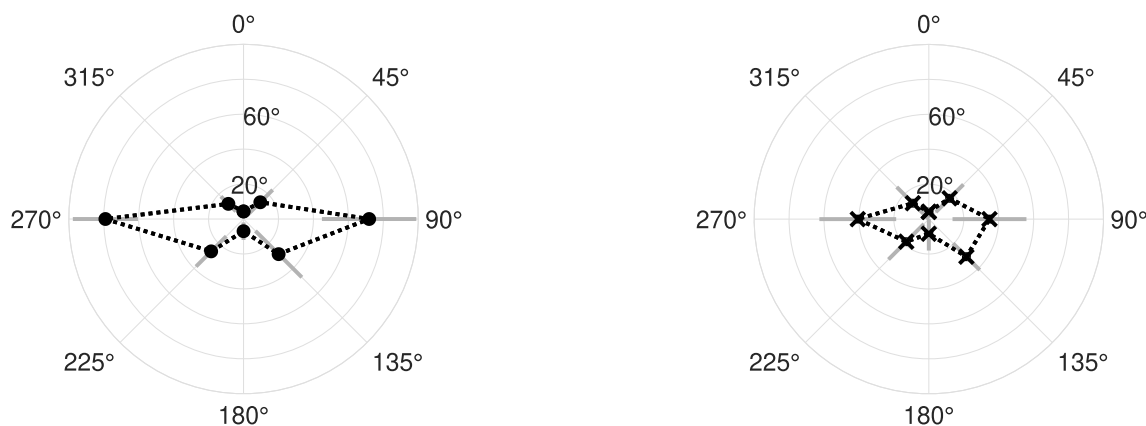

476 Figure 2:

477

478 Figure 2: Averaged root mean square error ($RMSE_{LOC}$) for the omnidirectional (OMNI, circles) and
479 pinna-imitating (PI, crosses) microphone modes. Left, Front-back confusions (FBCs) were excluded
480 from the error calculation whereas the right figure shows the $RMSE_{LOC}$ including FBCs. See
481 supplemental digital content 2, Tables 2 and 4 for numerical data including standard deviations and
482 median values.

483 Figure 3:

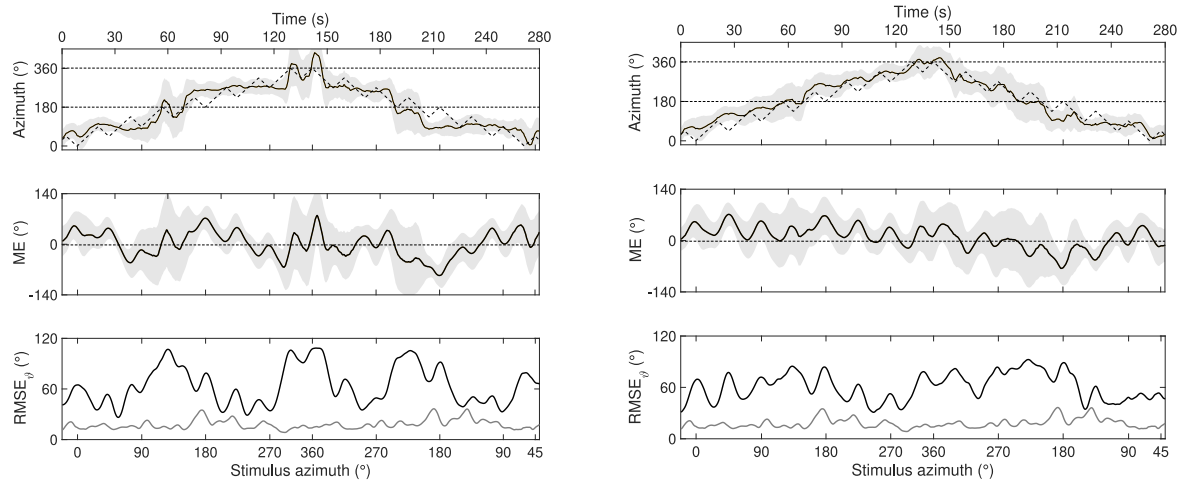

484

485 Figure 3: Minimum audible angles for the omnidirectional (OMNI, left figure) and pinna-imitating
486 (PI, right figure) microphone modes averaged across all subjects. The gray bars indicate ± 1 standard
487 deviation. See supplemental digital content 2, Tables 7 and 8 for a tabular summary.

488

489 **Figure 4:**

490

491 Figure 4: Sound-source tracking with the alternating movement trajectory including multiple changes
492 in direction. Plotted are the positions of the sound source and the averaged subject responses (as
493 indicated with the touchpad), the mean error (ME) and the root mean square error (RMSE _{θ}) averaged
494 across all the subjects for the omnidirectional (OMNI, left figure) and pinna-imitating (PI, right
495 figure) microphone modes. The nonhorizontal dotted lines in the top plots show the trajectory of the
496 stimulus, and the solid lines show the averaged stimulus position, which was indicated by the user.
497 The gray margins around the solid lines in the top and middle plots indicate ± 1 standard deviation.
498 The gray lines in the bottom plots indicate the performance of the normal-hearing subjects (Fischer
499 et al. 2019).
