## 1 **Abstract**

2 *Mycobacterium leprae*, the causative agent of leprosy, is an unculturable bacterium with a considerably  
3 reduced genome (3.27 Mb) compared to homologues mycobacteria from the same ancestry. *M. leprae*  
4 transmission is suggested to occur through aerosols but the exact mechanisms of infection remains  
5 unclear. In 2001, the genome of *M. leprae* was first described and subsequently four genotypes (1-4)  
6 and 16 subtypes (A-P) were identified providing means to study global transmission patterns for  
7 leprosy.

8 We investigated *M. leprae* carriage as well as infection in leprosy patients (n=60) and healthy  
9 household contacts (HHC; n=250) from Bangladesh using molecular detection of the bacterial element  
10 RLEP in nasal swabs (NS) and slit skin smears (SSS). In parallel, we explored bacterial strain diversity  
11 by whole-genome sequencing (WGS) and Sanger sequencing.

12 In the studied cohort in Bangladesh, *M. leprae* DNA was detected in 33.3% of NS and 22.2% of SSS of  
13 patients with bacillary index of 0 whilst in HHC 18.0% of NS and 12.3% of SSS were positive.

14 The majority of the *M. leprae* strains detected in this study belonged to genotype 1D (55%), followed  
15 by 1A (31%). Importantly, WGS allowed the identification of a new *M. leprae* genotype, designated  
16 1B-Bangladesh (14%), which clustered separately between the 1A and 1B strains. Moreover, we  
17 established that the genotype previously designated 1C, is not an independent subtype but clusters  
18 within the 1D genotype.

19 Intraindividual differences were present between the *M. leprae* strains obtained including mutations in  
20 hypermutated genes, suggesting mixed colonization/infection or in-host evolution.

21 In summary, we observed that *M. leprae* is present in asymptomatic contacts of leprosy patients fueling  
22 the concept that these individuals contribute to the current intensity of transmission. Our data therefore  
23 emphasize the importance of sensitive and specific tools allowing post-exposure prophylaxis targeted at  
24 *M. leprae*-infected or -colonized individuals.

## 1 Introduction

2 *Mycobacterium leprae* and the more recently discovered *Mycobacterium lepromatosis* (Han et al.,  
3 2008) are the causative agents of leprosy in humans as well as animals (Truman et al., 2011; Sharma  
4 et al., 2015; Avanzi et al., 2016; Honap et al., 2018; Schilling et al., 2019b; Tio-Coma et al., 2019).

5 Leprosy is a complex infectious disease often resulting in severe, life-long disabilities and still poses a  
6 serious health threat in low- and middle income countries (WHO, 2019). Despite the very limited *M.*  
7 *leprae* genome variability (Singh and Cole, 2011), the disease presents with characteristically  
8 different clinico-pathological forms (Ridley and Jopling, 1966) due to genetically dependent  
9 differences in the immune response to the pathogen, resulting in the WHO classification from  
10 paucibacillary (PB) to multibacillary (MB) leprosy (Kumar et al., 2017). Notwithstanding the efficacy  
11 of multidrug therapy (MDT), approximately 210,000 new cases are still annually diagnosed and this  
12 incidence rate has been stable over the last decade (WHO, 2019). Aerosol transmission via respiratory  
13 routes is generally assumed to be the most probable way of bacterial dissemination (Bratschi et al.,  
14 2015; Araujo et al., 2016). Besides bacterial exposure other risk factors have been shown to be  
15 associated with development of leprosy such as genetic polymorphisms (Mira et al., 2004; Zhang et  
16 al., 2009; Wang et al., 2015; Sales-Marques et al., 2017), the clinical type of the leprosy index case  
17 within a household, immunosuppression (Moet et al., 2004), and nutritional factors (Dwivedi et al.,  
18 2019).

19  
20 *M. leprae* is closely related to *Mycobacterium tuberculosis*, however, its genome has undergone a  
21 reductive evolution resulting in a genome of only 3.27 Mb compared to the 4.41 Mb of *M.*  
22 *tuberculosis*' (Cole et al., 2001). Part of the genes lost in *M. leprae* included vital metabolic activity,  
23 causing it to be an obligate intracellular pathogen which cannot be cultured in axenic media that  
24 requires support of a host to survive. This poses major limitations to obtain sufficient bacterial DNA  
25 for research purposes including whole genome sequencing (WGS). Nevertheless, in 2001 the genome

*M. leprae* genotypes in Bangladesh

1 of *M. leprae* was first published (Cole et al., 2001) leading to the classification of *M. leprae* into four  
2 main genotypes (1-4) (Monot et al., 2005) and subsequently further allocation into 16 subtypes (A-P)  
3 (Monot et al., 2009; Truman et al., 2011). The genome of *M. leprae* contains several repetitive  
4 elements such as RLEP which present 37 copies and has been widely applied in molecular diagnostics  
5 to specifically detect the presence of this mycobacterium (Donoghue et al., 2001; Truman et al., 2008;  
6 Martinez et al., 2011; Braet et al., 2018).

7 Single-nucleotide polymorphisms (SNP) genotyping and WGS are powerful approaches to investigate  
8 pathogen transmission as well as bacterial dissemination and evolution through genome  
9 characterization (Monot et al., 2005; Monot et al., 2009; Han and Silva, 2014). The limited variation  
10 observed in the *M. leprae* genome permits the reconstruction of historic human migration patterns and  
11 the origin of *M. leprae* (Donoghue, 2019). Over the years, several studies have contributed to the  
12 detection and characterization of *M. leprae* genomes originating from patients all around the world  
13 (Monot et al., 2005; Monot et al., 2009; Benjak et al., 2018) as well as from ancient skeletons (Suzuki  
14 et al., 2010; Schuenemann et al., 2013; Mendum et al., 2014; Krause-Kyora et al., 2018;  
15 Schuenemann et al., 2018), red squirrels (Avanzi et al., 2016; Schilling et al., 2019a; Tio-Coma et al.,  
16 2019), armadillos (Truman et al., 2011; Sharma et al., 2015), non-human primates (Honap et al.,  
17 2018) and soil (Lavania et al., 2006; Lavania et al., 2008; Turankar et al., 2012; Turankar et al., 2014;  
18 Turankar et al., 2016; Tió-Coma et al., 2019; Turankar et al., 2019). Moreover, skeleton remains have  
19 been successfully applied to retrospectively assess whether individuals who contributed to the care of  
20 leprosy patients such as the priest Petrus Donders, had developed leprosy (Van Dissel et al., 2019). In  
21 the last few years, new tools were developed allowing direct sequencing of *M. leprae* from various  
22 types of clinical isolates (Avanzi et al., 2016; Benjak et al., 2018; Schuenemann et al.,  
23 2018). However, these methods were never applied on challenging samples such as slit skin smears  
24 (SSS) and nasal swabs (NS) containing a low amount of bacterial DNA compared to skin lesions of  
25 patients.

*M. leprae* genotypes in Bangladesh

1

2 Household contacts of leprosy patients are a high risk group for developing the disease (Richardus et  
3 al., 2019), and might serve as asymptomatic carriers contributing to bacterial dissemination. PCR and  
4 quantitative PCR (qPCR) are reliable techniques to detect *M. leprae* DNA and have been proposed as  
5 tools for early diagnosis of leprosy, particularly among household contacts of newly diagnosed  
6 patients (Gama et al., 2018; Gama et al., 2019). In Brazil, *M. leprae* DNA has been detected in 15.9%  
7 of healthy household contacts (HHC) in SSS, 9.7% in blood (Gama et al., 2018) and 8.9 to 49.0% in  
8 NS (Brito e Cabral et al., 2013; Araujo et al., 2016; Carvalho et al., 2018). Other studies from India,  
9 Indonesia and Colombia reported 21% of *M. leprae* positivity in SSS of HHC (Turankar et al., 2014),  
10 7.8% (van Beers et al., 1994) and 16.0% in NS (Romero-Montoya et al., 2017).

11 Detection of host markers, such as serum IgM levels of anti-*M. leprae* phenolic glycolipid I (PGL-I),  
12 represents an alternative approach to diagnose infected individuals (Penna et al., 2016; van Hooij et  
13 al., 2017; Barbieri et al., 2019). However, although detection of *M. leprae* DNA as well as antibodies  
14 against PGL-I indicate infection with *M. leprae*, this does not necessarily result in disease. Thus,  
15 these tests alone are not sufficient to identify the complete leprosy spectrum (Spencer and Brennan,  
16 2011; van Hooij et al., 2019).

17

18 Bangladesh is a leprosy endemic country reporting up to 3,729 new leprosy cases in 2018 (WHO,  
19 2019). However, *M. leprae* whole genomes (n=4) from Bangladesh, have only been described in one  
20 study (Monot et al., 2009) in which genotypes 1A, 1C and 1D were identified. To gain more insight  
21 into *M. leprae* genome variation and transmission routes in endemic areas in Bangladesh as well as  
22 the potential role of asymptomatic carriers, we further explored the diversity and transmission of *M.*  
23 *leprae* in four districts of the northwest of Bangladesh. We collected SSS and NS of 31 leprosy  
24 patients with a high bacterial load as well as 279 of their household contacts and characterized *M.*  
25 *leprae* DNA by WGS or Sanger sequencing. The resulting genotypes were correlated to the subjects'

*M. leprae* genotypes in Bangladesh

- 1 GIS location. Additionally, this is the first study to examine *M. leprae* DNA detection in comparison
- 2 to anti-PGL-I IgM levels in plasma measured by up-converting phosphor lateral flow assays (UCP-
- 3 LFAs).

## 1 **Materials and methods**

### 2 **Study design and sample collection**

3 Newly diagnosed leprosy patients (index case, n=31) with bacteriological index (BI)  $\geq$  2 and 3-15  
4 household contacts of each index case (n=279) were recruited between July 2017 and May 2018 (Table  
5 S1, Supplementary Data 1) in four districts of Bangladesh (Nilphamari, Rangpur, Panchagar and  
6 Thakurgaon). Patients with five or fewer skin lesions and BI 0 were grouped as PB leprosy. Patients  
7 with more than five skin lesions were grouped as MB leprosy and BI was determined. The prevalence  
8 in the districts where this study was performed was 0.9 per 10,000 and the new case detection rate 1.18  
9 per 10,000 (Rural health program, the leprosy mission Bangladesh, yearly district activity report 2018).  
10 For *M. leprae* detection and characterization, SSS from 2-3 sites of the earlobe and NS (tip wrapped  
11 with traditional fiber, CLASSIQSwabs, Copan, Brescia, Italy) were collected and stored in 1 ml 70%  
12 ethanol at -20 °C until further use. For immunological analysis, plasma was collected (van Hooij et al.,  
13 2017; van Hooij et al., 2018; van Hooij et al., 2019).

14 Subjects included in the study were followed up for surveillance of new case occurrence for  $\geq$  24  
15 months after sample collection.

### 16 **Ethics Statement**

17 Subjects were recruited following the Helsinki Declaration (2008 revision). The National Research  
18 Ethics Committee approved the study (BMRC/NREC/2016-2019/214) and participants were informed  
19 about the study objectives, the samples and their right to refuse to take part or withdraw without  
20 consequences for their treatment. All subjects gave informed consent before enrollment and treatment  
21 was provided according to national guidelines.

### 22 **DNA isolation from slit skin smears and nasal swabs**

23 DNA was isolated using DNeasy Blood & Tissue Kit (Qiagen, Valencia, CA) as per manufacturer's  
24 instructions with minor modifications. Briefly, tubes containing 1 ml 70% ethanol and SSS were

*M. leprae* genotypes in Bangladesh

1 vortexed for 15 seconds. SSS were removed and tubes were centrifuged for 15 minutes at 14000 rpm.  
2 Supernatants were removed and buffer ATL (200 µl) and proteinase K (20 µl) added. NS were  
3 transferred to new microtubes and the microtubes containing the remaining ethanol were centrifuged at  
4 14000 rpm for 15 minutes. Supernatants were removed and NS were inserted again in the tubes, prior  
5 addition of ATL buffer (400 µl) and proteinase K (20 µl). SSS and NS samples were incubated at 56 °C  
6 for 1 h at 1100 rpm. Next, AL buffer (200 µl) was added and incubated at 70 °C for 10 min at 1400  
7 rpm. Column extraction was performed after absolute ethanol precipitation (200 µl) as per  
8 manufacturer's instructions. To avoid cross contamination tweezers were cleaned first with hydrogen  
9 peroxide and then with ethanol between samples.

## 10 **RLEP PCR and qPCR**

11 RLEP PCR (Donoghue et al., 2001) was performed as previously described (Tió-Coma et al., 2019).  
12 Briefly, the 129 bp RLEP sequence was amplified in 50 µl by addition of 10 µl 5x Gotaq® Flexi buffer  
13 (Promega, Madison, WI), 5 µl MgCl<sub>2</sub> (25 mM), 2 µl dNTP mix (5 mM), 0.25 µl Gotaq® G2 Flexi  
14 DNA Polymerase (5 u/µl), 5 µl (2 µM) forward and reverse primers (Table S2) and 5 µl template  
15 DNA, water (negative control) or *M. leprae* DNA (Br4923 or Thai-53 DNA, BEI Resources, Manassas,  
16 VA) as positive control. PCR mixes were subjected to 2 min at 95 °C followed by 40 cycles of 30 s at  
17 95 °C, 30 s at 65°C and 30 s at 72 °C and a final extension of 10 min at 72 °C. PCR products (15µl)  
18 were used for electrophoresis in a 3.5% agarose gel at 130V. Amplified DNA was visualized by Midori  
19 Green Advance staining (Nippon Genetics Europe, Dueren, Germany) using iBright™ FL1000  
20 Imaging System (Invitrogen, Carlsbad, CA).

21 Samples from index cases and a selectin of contacts for sequencing were also evaluated by qPCR  
22 (Martinez et al., 2009). The mix included 12.5 µl TaqMan Universal Master Mix II (Applied  
23 Biosystems, Foster City, CA), 0.5 µl (25 µM) forward and reverse primers (Table S2), 0.5 µl (10 µM)  
24 TaqMan probe (Table S2) and 5 µl template DNA were mixed in a final volume of 25 µl. DNA was

## *M. leprae* genotypes in Bangladesh

1 amplified using the following profile: 2 min at 50°C and 10 min at 95°C followed by 40 cycles of 15 s  
2 at 95°C and 1 min at 60°C with a QuantStudio 6 Flex Real-Time PCR System (Applied Biosystems).  
3 Presence of *M. leprae* DNA was considered if a sample was positive for RLEP qPCR with a cycle  
4 threshold (Ct) lower than 37.5 or was positive for RLEP PCR at least in two out of three indecently  
5 performed PCRs to avoid false positives.

## 6 **Library preparation and enrichment**

7 A total of 60 DNA extracts were selected for sequencing, including 30 from SSS and 30 from NS  
8 (Figure S1, Supplementary Data 1). At least one sample from each index leprosy patient was selected  
9 as well as RLEP positive samples of HHC or patients who were household contacts of the index case  
10 (selection based on Ct value and household overlap). A maximum of 1µg of DNA in a final volume of  
11 50µL was mechanically fragmented to 300 bp using the S220 Focused-ultrasonicator (Covaris)  
12 following the manufacturer's recommendations and cleaned-up using a 1.8x ratio of AMPure beads. Up  
13 to 1µg of fragmented DNA was used to prepare indexed libraries using the Kapa Hyperprep kit  
14 (Roche) and the Kapa dual-indexed adapter kit as previously described (Benjak et al., 2018) followed  
15 by two rounds of amplification. All libraries were quantified using the Qubit fluorimeter (Thermo  
16 Fisher Scientific, Waltham, MA), and the fragment size distribution was assessed using a fragment  
17 analyzer.

18 Libraries were target enriched for the *M. leprae* genome using a custom MYbaits Whole Genome  
19 Enrichment kit (ArborBioscience) as previously described (Honap et al., 2018). Briefly, biotinylated  
20 RNA baits were prepared using DNA from *M. leprae* Br4923. A total of 1500 ng of each amplified  
21 libraries was used for enrichment. Each library was pooled prior to enrichment with another library  
22 with similar qPCR Ct value. Enrichment was conducted according to the MYbaits protocol with the  
23 hybridization being carried out at 65 °C for 24 hours. After elution, all pools were amplified using the

## *M. leprae* genotypes in Bangladesh

1 Kapa amplification kit with universal P5 and P7 primers (Roche). All amplification reactions were  
2 cleaned up using the AMPure beads (1X ratio).

### 3 **Illumina sequencing**

4 Pools were multiplexed on one lane of a NextSeq instrument with a total amount of 20-30 million reads  
5 per pools. Some libraries were deep sequenced based on the mapping statistics obtained in the first run.  
6 Raw reads were processed and aligned to *M. leprae* TN reference genome (GenBank accession number  
7 AL450380.1) as previously described using an in-house pipeline (Benjak et al., 2018). A minimum  
8 depth coverage of 5 was considered for further phylogenetic analysis.

### 9 **Sequencing analysis**

10 Genome comparison was based on analysis of SNPs (analyzed with VarScan v2.3.9(Koboldt et al.,  
11 2012)) and Indels (analyzed with Platypus v0.8.171(Rimmer et al., 2014)) as formerly reported (Benjak  
12 et al., 2018). The newly sequenced *M. leprae* genomes were aligned with 232 genomes available in  
13 public databases (Schuenemann et al., 2018; Avanzi et al., In press). Sites below 90 and above 10%  
14 alignment difference were also reported. A comparison to 259 *M. leprae* genomes (including 27 new  
15 genomes) allowed the identification of unique SNPs per index case. Each candidate SNP or Indel was  
16 checked manually on Integrative Genomics Viewer (Robinson et al., 2011).

### 17 **Genotyping and antimicrobial resistance by Sanger sequencing**

18 To further characterize the *M. leprae* strains for which the whole genome sequence was not obtained,  
19 specific primers were designed to perform Sanger sequencing based on unique SNPs (Table S3 and S4)  
20 of each index case strain. Additionally, Sanger sequencing was performed after amplifying several loci  
21 (Table S2) to subtype the genomes based on standard the *M. leprae* classification (Monot et al., 2009;  
22 Truman et al., 2011) and to determine antimicrobial resistance to rifampicin (*rpoB*), dapsone (*folP1*) or  
23 ofloxacin (*gyrA*). PCRs were performed with 5 µl of template DNA using the aforementioned PCR

*M. leprae* genotypes in Bangladesh

1 mixes. DNA was denatured for 2 minutes at 95°C, followed by 45 cycles of 30 s at 95°C, 30 s at 50-58  
2 °C and 30 s at 72 °C and a final extension cycle of 10 min at 72°C. PCR products were resolved by  
3 agarose gel electrophoresis as explained above. PCR products showing a band were purified prior to  
4 sequencing using the Wizard SV Gel and PCR Clean-Up System (Promega). Sequencing was  
5 performed on the ABI3730xl system (Applied Biosystems) using the BigDye Terminator Cycle  
6 Sequencing Kit (Thermo Fisher Scientific). Sequences were analyzed using Bioedit v7.0.5.3.

7 **Anti-PGL-I UCP-LFA**

8 UCP-LFAs were performed using the LUMC developed LFA based on luminescent up-converting  
9 reporter particles for quantitative detection of anti-*M. leprae* PGL-I IgM as previously described (van  
10 Hooij et al., 2017; van Hooij et al., 2018; van Hooij et al., 2019). Plasma samples (n=308, 2 samples  
11 excluded due to labeling mistake) were thawed and diluted (1:50) in assay buffer. Strips were placed in  
12 microtiter plate wells containing 50 µl diluted samples and target specific UCP conjugate (PGL-I, 400  
13 ng). Immunochromatography continued for at least 30 min until dry. Scanning of the LFA strips was  
14 performed by LFA strip readers adapted for measurement of the UCP label (UPCON; Labrox, Finland).  
15 Results are displayed as the Ratio (R) value between Test and Flow-Control signal based on relative  
16 fluorescence units (RFUs) measured at the respective lines. The threshold for positivity for the αPGL-I  
17 UCP-LFA was 0.10.

## 1 **Results**

### 2 ***M. leprae* detection in patients and healthy household contacts**

3 At diagnosis of the index cases and recruitment of contacts into this study 250 household contacts had  
4 no signs or symptoms of leprosy or other diseases (HHC), whereas 22 household contacts were  
5 diagnosed as PB and seven as MB patients (Table S1, Supplementary Data 1).

6 Presence of *M. leprae* DNA was determined by RLEP PCR or qPCR in SSS and NS of leprosy patients  
7 and HHC (Figure 1, Supplementary Data 1): as expected in MB patients with BI 2-6 *M. leprae* DNA  
8 was almost always detectable in both SSS (96.8%) and NS (90.9%). This was much lower in PB and  
9 MB patients with BI 0 ranging from 22.2% in SSS to 33.3% in NS. Positivity rates in HHC were not  
10 very different from those observed for PB and MB patients with BI 0, with 12.3% positive samples in  
11 SSS and 18.0% in NS. Moreover, the overall Ct range was lower for SSS [16.3-37.1] compared to NS  
12 [20.1-39.4] showing that SSS contained more *M. leprae* DNA and is a preferred sample for its  
13 detection (Supplementary Data 1).

14 HHC (n=250) were followed up clinically for  $\geq 24$  months after sample collection and four of them  
15 developed leprosy within the first year. RLEP PCR performed on DNA isolated before disease  
16 occurrence showed a positive result from SSS in one patient (5 months before diagnosis) and a positive  
17 result from NS in another (8 months before diagnosis). All of the new cases developed PB leprosy with  
18 BI of 0 and three were genetically related to the index case (parent and child of index case H03 and  
19 second degree relative of index case H30) and one was the spouse (index case H10).

### 20 **Genome typing and antimicrobial resistance**

21 *M. leprae* genomes of SSS and NS were genotyped by WGS or Sanger sequencing. A total of 60  
22 samples (30 SSS and 30 NS) were selected for WGS with an RLEP qPCR Ct ranging from 16.2 to 37.2  
23 (Figure S1, Supplementary Data 1). A total of 27 samples from 21 subjects (21 SSS and 6 NS) were

*M. leprae* genotypes in Bangladesh

1 successfully sequenced with a coverage  $\geq 5$  (Table S5). The limiting Ct value was 26.2 for SSS and  
2 24.2 for NS.

3 On applying the genotyping system described by (Monot et al., 2009; Truman et al., 2011), the  
4 following genotypes were found for these 21 subjects: 1A (n=5), 1B (n=4), 1C (n=3) and 1D (n=9).  
5 Interestingly, the four newly sequenced 1B genotype strains do not cluster with the two previously  
6 described 1B strains from Yemen and Martinique (Figure 2). Instead, they form a new cluster in the  
7 phylogenetic tree located between genotypes the 1A and 1B, which we refer to as 1B-Bangladesh  
8 (Figure 2, blue, Supplementary Data 1). Using Sanger sequencing, the *M. leprae* strain for eight  
9 additional individuals were determined as 1A (n=4) or 1D (n=4). Three subjects carried genotype 1 but  
10 subtype could not be established (Supplementary Data 1).

11 The SNP used to differentiate genotype 1C (A61425G; Met90Thr, mutated in genotypes 1D and 2-4) is  
12 located at *esxA*. In contrast to previous observations (Monot et al., 2009; Truman et al., 2011), we  
13 found that this position is not phylogenetically informative as it is also found unmutated (A; Met) in  
14 strains from the genotype 3I and 2E (Figure 2, green, Supplementary Data 2). Moreover, the 1C strains  
15 clustered in the middle of the 1D group suggesting that the previously described genotype 1C is part of  
16 the 1D genotype.

17 Finally, antimicrobial resistance was assessed in all genotyped strains either by WGS or Sanger  
18 sequencing. The latter was successful on 18 samples for *rpoB*, five sample for *folP1* and 15 samples for  
19 *gyrA* (Supplementary Data 1). None of the strains with a complete genome harbored drug-resistance  
20 mutations. One NS sample containing a missense mutation in the *rpoB* gene (Ser456Thr) in 50% of the  
21 sequences potentially leading to antimicrobial resistance (2017) was identified by Sanger sequencing.  
22 Moreover, although not causing resistance, up to two silent mutations in three different positions of the  
23 *rpoB* gene relevant for antimicrobial resistance (432, 441 and 456) were also observed in several  
24 subjects.

## 1 **Distribution and possible transmission of *M. leprae* genotypes**

2 The most prevalent *M. leprae* genotype in the studied area of Bangladesh is 1D, found in 55% of the  
3 individuals (n=16, Table 1, Supplementary Data 1), followed by 1A in 31% (n=9), and 1B-Bangladesh  
4 in 14% (n=4). Genotype 1D is the most widely distributed throughout the whole area studied (Figure 3,  
5 blue and purple), whilst genotypes 1A and the here identified genotype 1B-Bangladesh are only  
6 observed in the eastern area (green and orange respectively). The latter genotype was found in 4  
7 individuals: two from the same household and two unrelated subjects residing 56, 51 and 11 km from  
8 each other. However, due to privacy regulations on patient information to third parties it could not be  
9 established whether subjects in different households had had contact with any of the others.

10 In a total of four households the same *M. leprae* genotype was detected in two individuals  
11 (Supplementary Data 1). In the first household, both subjects were MB patients and WGS showed no  
12 genetic variation at all between both patients' genomes (RB001 and RB003, 1B-Bangladesh genotype,  
13 Supplementary Data 2). In the second household with two MB patients, the *M. leprae* whole genome  
14 was only obtained from the index case but the same genotype, 1A, and a strain-specific SNP of the  
15 index case (Table S3 and S4) was also identified by Sanger sequencing in the other patient (RB182 and  
16 RB266). In the last two households, the genotype of strains from both MB index cases' were  
17 determined by WGS (RB030, genotype 1D) and, by Sanger sequencing (RB065, genotype 1D-*esxA*),  
18 while the *M. leprae* genotype 1 was located in the NS of both HHC but no further subtyping was  
19 possible.

## 20 **Comparison of *M. leprae* genomes from SSS and NS**

21 *M. leprae* whole genomes of six patients were successfully recovered from both SSS and NS. Genomic  
22 comparison showed no differences between DNA from SSS and NS for two patients: RB001-RN001  
23 (genotype 1B-Bangladesh) and RB048-RN059 (genotype 1D-*esxA*, Supplementary Data 2, Figure 2).

*M. leprae* genotypes in Bangladesh

1 In a third patient (RB073-RN084, genotype 1A), both strains were identical except that in the NS strain  
2 13% of 32 reads in *mlI512* harbored a T1824441C (Gly56Asp) (Table 2). Interestingly, *mlI512* which  
3 encodes a ribonuclease J is one of the most mutated genes among all *M. leprae* strains (Benjak et al.,  
4 2018) and mutations at this gene were also observed in two different patients: in the NS of RN022-  
5 RB053 (genotype 1D) 28% of 115 reads had a mutated allele (G1823127A; Ser494Leu) and 8.5% of  
6 59 reads had an insertion of a C at position 1823614 probably leading to a deleterious frameshift; in the  
7 SSS of RB074-RN095 (genotype 1B-Bangladesh) 91% of 158 reads presented a missense mutation  
8 (G1823098A; Leu504Phe). Interestingly, RB074 harbored a G660474C mutation in *metK*, a probable  
9 methionine adenosyl-transferase, which was also found in 76% of 16 reads of the NS and is uniquely  
10 found in this subject's *M. leprae* genomes. Additionally, RN095 also displayed mutations at several  
11 positions in *mlI750* (a putative nucleotide cyclase): 60% of 40 reads had C2116695A (Pro100Thr),  
12 23% of 40 reads had A2116670G (Gln108Arg) and 26% of 27 reads had G2116670A mutation  
13 (Arg168His). These positions were partially or totally mutated in other strains from different  
14 genotypes: SM1 (100% Pro100Ser; genotype 4), MI9-81 (Mali, 30% Arg168His; genotype 4N) and  
15 Md05036 (Madagascar, 90% Gln108Arg, genotype 1D-Malagasy) (Benjak et al., 2018; Avanzi et al.,  
16 In press).

17 The patient with the *M. leprae* strains that were the most genetically different between the NS and SSS  
18 carried the genotype 1B-Bangladesh (RB069 and RN165). The NS strain had a mixed population in  
19 *glpQ* (25% of 257 reads C9231T, Leu34Phe) and *mlI752* (16% of 307 reads C2121552T, Val226Ile).  
20 These genes encode a glycerophosphoryl diester phosphodiesterase and a conserved hypothetical  
21 protein. Notably, *mlI752* is also one of the most hypermutated genes in *M. leprae* (Benjak et al., 2018).  
22 For 11 patients a whole genome sequence was recovered only from SSS but Sanger sequencing was  
23 successfully performed to identify the subtype in NS. The same subtype observed in SSS was also  
24 found in the NS of these 11 patients. Moreover, unique *M. leprae* SNPs identified in the genomes of

1 the SSS (Table S3 and S4) were also detected in seven of the genomes of the NS of these patients  
2 (Supplementary Data 1).

### 3 **Combining host and pathogen detection**

4 Anti-PGL-I IgM levels were determined in plasma of 308 subjects. All MB patients with BI 2-6 (n=33)  
5 showed high levels for anti-PGL-I IgM (Table 3) in line with the general consensus (Geluk et al., 2011;  
6 van Hooij et al., 2017). Out of the patients (both MB and PB) with BI 0 (n=27), nine (33.3%) were  
7 positive for anti-PGL-I IgM. Similarly, 36.8% of HHC showed positivity (n=92). From these 92  
8 positive individuals, 70 were neither positive for SSS nor NS RLEP PCR (Supplementary Data 1).

9 Of the four contacts who developed leprosy within the first year after sample collection, two were  
10 positive for anti-PGL-I IgM whilst negative for RLEP PCRs 10 and 12 months before diagnosis. Since  
11 the two other subjects had a positive RLEP PCR in SSS or NS 5 or 8 months before diagnosis, it can be  
12 concluded that all of the new cases showed positivity either for host- or pathogen-associated  
13 diagnostics 5-12 months before developing disease.

14 Individual anti-PGL-I levels were compared to RLEP Ct values in SSS and NS samples (Figure 4),  
15 showing an expected negative correlation between anti-PGL-I ratio and Ct value since both values are  
16 associated with BI. A subtle difference can be observed in the correlation between anti-PGL-I IgM  
17 levels and RLEP Ct if the qPCR was performed on either SSS or NS DNA, with a coefficient of  
18 determination ( $R^2$ ) 0.73 and 0.69 respectively.

## 1 Discussion

2 In this study we investigated *M. leprae* transmission patterns in Bangladesh by detecting and  
3 sequencing *M. leprae* DNA derived from SSS and NS of patients and their household members. Our  
4 data represents the first report of *M. leprae* DNA detection in HHC from Bangladesh. We observed  
5 moderate positivity in HHC which was similar to positivity of leprosy patients with BI 0. A new  
6 genotype, 1B-Bangladesh, was sequenced and we showed that the previously described 1C genotype is  
7 part of the 1D group. Additionally, a negative correlation between RLEP Ct values indicating the  
8 amount of *M. leprae* DNA and anti-PGL-I IgM levels was observed.

9  
10 *M. leprae* DNA detection frequency in HHC from Bangladesh (12.3% in SSS and 18.0% in NS) was in  
11 line with previous studies conducted in several hyperendemic areas of Brazil, Colombia and Indonesia  
12 (van Beers et al., 1994; Brito e Cabral et al., 2013; Romero-Montoya et al., 2017; Carvalho et al., 2018;  
13 Gama et al., 2018). In India higher positivity (21%) in SSS of HHC was reported (Turankar et al.,  
14 2014) whereas in a Brazilian study from Uberlandia, up to 49% of positivity in NS was observed  
15 (Araujo et al., 2016). Three factors may limit the translation of these high positive results from India  
16 and Brazil to our study: i) the sample sizes of the Indian and Brazilian studies were smaller (n=28 and  
17 n=104, respectively versus n=250 HHC in this study); ii) we conducted a more stringent approach by  
18 testing the samples in three independent PCRs; and iii) the epidemiology and incidence of MB cases in  
19 India and Brazil differ from the studied area in Bangladesh where MB leprosy cases occur less  
20 frequently than PB and also usually display a low BI (Richardus et al., 2017).

21 *M. leprae* DNA in the nose does not indicate disease but (transient) colonization whilst presence of *M.*  
22 *leprae* in SSS indicates infection. Thus, the higher RLEP PCR positivity in NS compared to SSS in  
23 patients with BI 0 and HHC likely represents the (virtual) absence of bacteria causing infection in these  
24 individuals despite colonization.

*M. leprae* genotypes in Bangladesh

1 A longitudinal study conducted in Brazil (Manta et al., 2019), investigated SSS from 995 HHC by  
2 qPCR including follow-up for at least 3 years with occurrence of five new cases. The authors reported  
3 20% qPCR positivity in HHC representing future new cases compared to 9% in HHC without disease.  
4 However, this difference was not significant. In line with that study, we found that *M. leprae* DNA  
5 detection was slightly higher (25% vs 18% in NS and 25% vs 12% in SSS) in contacts who developed  
6 disease compared to those who did not. Additionally, we determined anti-PGL-I IgM levels, which  
7 correlated well with Ct qPCR values. Notwithstanding this correlation, serology provided added value:  
8 when positivity in any of the three techniques was considered (NS PCR, SSS PCR or anti PGL-I), all of  
9 the contacts (n=4) who developed leprosy within the first year after sample collection, were identified.  
10 In agreement with this, a combination of host and pathogen markers was previously integrated in a  
11 machine learning model using qPCR and serological data (antibodies against LID-1 or ND-O-LID)  
12 (Gama et al., 2019) to identify prospective leprosy patients among contacts leading to an increased  
13 sensitivity in diagnosis, particularly in PB leprosy. It is of note that in our study, three of the four  
14 contacts who developed leprosy were genetically related to the index cases in their households,  
15 stressing the previously described role of genetic inheritance in the development of leprosy (Mira et al.,  
16 2004; Zhang et al., 2009; Wang et al., 2015; Sales-Marques et al., 2017; Uaska Sartori et al., 2020). For  
17 this reason, the association between leprosy and the genetics of this Bangladeshi population is currently  
18 being studied.

19  
20 Genotype 1 was identified in all the *M. leprae* genomes retrieved from Bangladesh, consistent with  
21 previous data from (Monot et al., 2009). In Bangladesh, leprosy was likely introduced through the  
22 southern Asian route (genotype 1) leading to the spread of *M. leprae* into the Indian subcontinent,  
23 Indonesia and the Philippines (Monot et al., 2009; Benjak et al., 2018). Subtype 1D was predominantly  
24 present in Bangladesh but in addition we detected 1A and identified a new 1B-Bangladesh genotype.  
25 This new genotype is thus far restricted to Bangladesh and two of the four individuals carrying this

*M. leprae* genotypes in Bangladesh

1 strain were part of the same household whilst the other two did not have any relationship with each  
2 other and were located in different areas with a distance of up to 56 km between them. This suggests  
3 that this new genotype could be a common subtype in Bangladesh although additional studies are  
4 required to confirm this. Thus, it is of interest to include the 1B-Bangladesh SNP specific primers in  
5 future epidemiological studies, particularly in other (neighbouring) Asian countries such as India where  
6 genotype 1 is widely established (Monot et al., 2009).

7 In contrast to the general belief (Monot et al., 2009; Truman et al., 2011), we observed that subtype 1C  
8 does not form an independent subtype but actually belongs to subtype 1D. SNP61425 used to  
9 distinguish genotypes 1A-C is located at *esxA* encoding the virulence factor ESAT-6 (Monot et al.,  
10 2009). The Esx protein family also revealed high diversity in the more pathogenic mycobacterium, *M.*  
11 *tuberculosis* (Uplekar et al., 2011), and is involved in host-pathogen interaction. Of note is that ESAT-  
12 6 (ML0049) is a potent T-cell antigen (Geluk et al., 2002; Geluk et al., 2004), thus mutations in *esxA*  
13 gene might indicate drift due to immune pressure potentially explaining the occurrence of mutations at  
14 SNP61425 in different genotypes.

15  
16 In a recent survey in 19 countries during 2009-2015 (Cambau et al., 2018), 8% of the cases presented  
17 mutations resulting in antimicrobial resistance and resistance to up to two different drugs was detected.  
18 In our study, which is the first investigating *M. leprae* drug resistance in Bangladesh, we detected no  
19 resistance by WGS, however, a partial missense mutation in the codon for Ser456 of the *rpoB* gene  
20 potentially leading to rifampicin resistance (n=1) was observed by Sanger sequencing. This could be  
21 the result of a mixed infection or an emerging mutation of the *M. leprae* strain occurring in the patient.  
22 Silent mutations in the *rpoB* gene were detected in several locations, which indicates that mutations do  
23 occur, and this may eventually lead to missense mutations conferring antimicrobial resistance.  
24 However, drug resistance is not only induced by genetic mutations in drug targets, efflux systems  
25 resulting in antimicrobial resistance have also been described for *M. leprae* (Machado et al., 2018).

*M. leprae* genotypes in Bangladesh

1 This mechanism of drug resistance is unnoticed in genomic tests and needs to be further investigated  
2 for leprosy especially in the light of the huge efforts recently initiated and WHO-endorsed for post-  
3 exposure prophylaxis (PEP) using antibiotic regimens (Barth-Jaeggi et al., 2016; Mieras et al., 2018;  
4 Richardus et al., 2019).

5

6 Despite our finding that NS samples were more frequently positive for *M. leprae* DNA, recovery of *M.*  
7 *leprae* whole genomes from SSS has proven to be more successful than from NS. This is due to the  
8 higher number of bacteria in SSS of patients. However, the importance of genotyping NS as well as  
9 skin biopsies or SSS to better understand transmission has been previously discussed (Fontes et al.,  
10 2017), as the nasal respiratory route remains one of the most plausible modes of infection (Bratschi et  
11 al., 2015; Araujo et al., 2016). In a recent study, skin biopsies and NS of patients were compared by  
12 VNTR typing and the authors found that out of 38 patients, differences between SSS and NS in seven  
13 loci were observed in 33 patients (Lima et al., 2016). Although the *M. leprae* genomes from SSS and  
14 NS analysed in our study were almost identical, we observed that genomes obtained from NS  
15 harboured more mutations, especially in previously reported (Benjak et al., 2018) hypermutated genes.  
16 This could be an indication of in-host evolution in the nasal mucosa, mixed infection or mixed  
17 colonization. Thus, it may imply that colonization occurred with two different strains causing a co-  
18 infection or that one is present, likely from a later colonization, but does not cause the disease.

19 The presence of mixed infections emphasises once more the importance of monitoring asymptomatic  
20 carriers, who may contribute to the spread of the pathogen. Therefore, providing PEP only to the  
21 (close) contacts of leprosy patients might not be sufficient to stop transmission. Instead, an approach  
22 including the entire community but targeting only individuals testing positive for *M. leprae* DNA or  
23 host immune markers associated to *M. leprae* infection, would represent a preferred strategy for PEP.

## 1 **Data availability**

2 Sequence data are available from the NCBI Sequence Read Archive (SRA) under the bioprojects  
3 PRJNA605605 and PRJNA592722, biosamples SAMN14072760-775 and SAMN13438761-771.

## 1 **Tables**

2 **Table 1. *M. leprae* genotypes identified in Bangladesh.**

Genotype	Number of individual	%
1A	9	31.0
1B-Bangladesh	4	13.8
1D	13	44.8
1D- <i>esxA</i>	3	10.4
1*	3	

3 *M. leprae* genotypes identified in patients and contacts from Bangladesh and the percentage of each  
4 subtype are shown. *M. leprae* DNA was isolated from slit skin smears (SSS) and/or nasal swabs (NS).  
5 Genotypes were determined by Whole Genome Sequencing (WGS) or Sanger sequencing according to  
6 (Monot et al., 2009; Truman et al., 2011). The new subtype 1B-Bangladesh was identified by WGS and  
7 primers were then designed for use in Sanger sequencing (Table S5). 1D-*esxA* is 1D subtype containing  
8 an A at SNP61425 in the *esxA* gene, traditionally grouped as 1C (Monot et al., 2009; Truman et al.,  
9 2011). This SNP is also found in strains from the genotype 3I and 2E (Figure 2, green). 1\* are samples  
10 with genotype 1 for which the subtype could not be determined due to DNA concentration limit.

*M. leprae* genotypes in Bangladesh

1 **Table 2. Intraindividual *M. leprae* genomic differences.**

Samples	Mutation	Gene	% reads		Aligned	
			SSS	NS	reads SSS	reads NS
<b>RB073-RN084</b>	T1824441C; Gly56Asp	<i>ml1512</i>			13%	32
<b>RB053-RN022</b>	G1823127A; Ser494Leu	<i>ml1512</i>			28%	115
	1823614_1823615insC	<i>ml1512</i>			8.5%	59
<b>RB074-RN095</b>	G1823098A; Leu504Phe	<i>ml1512</i>	91%	158		
	G660474C; Val252Leu	<i>metK</i>	100%	196	76%	16
	C2116695A; Pro100Thr	<i>ml1750</i>			60%	40
	A2116670G; Gln108Arg	<i>ml1750</i>			23%	40
	G2116695A; Arg168His	<i>ml1750</i>			26%	27
<b>RB069-RN165</b>	C9231T; Leu34Phe	<i>glpQ</i>			25%	257
	C2121552T; Val226Ile	<i>ml1752</i>			16%	307

2 Genomic differences between *M. leprae* genomes obtained from slit skin smears (SSS) and nasal swabs  
3 (NS) of the same MB patient. Percentage of mutated reads and total number of reads aligned at the  
4 position of the mutation. No differences were found between the SSS and NS genomes of two patients:  
5 RB001-RN001 and RB048-RN059.

1 **Table 3. Anti-PGL-I IgM positivity.**

Genotype	Number of positive individual	% of positivity
MB patients BI 2-6 (n=33)	33	100.0
Patients BI 0 (n=27)	9	33.3
Healthy household contacts (n=250)	92	36.8

2 Anti-PGL-I antibody levels were measured by up-converting phosphor lateral flow assay specific for  
3 *M. leprae* PGL-I IgM antibodies (UCP-LFA) using the Ratio (R) of the Test (T) and flow control (FC)  
4 lines as units. Ratios of  $\geq 0.10$  were considered positive.

## 1 **Figure captions**

2 **Figure 1. Study design, RLEP positivity and genotyped samples.** Flow diagram providing an  
3 overview of the subjects recruited for this study. Slit skin smears (SSS) and nasal swabs (NS) collected  
4 per group; healthy household contacts (HHC), paucibacillary (PB) or multibacillary (MB) patients with  
5 BI 0, and MB patients with a bacteriological index (BI) 2-6. MB patients with BI 1 were not diagnosed  
6 within the course of this study. DNA was isolated from SSS and NS and screened for *M. leprae* DNA  
7 by RLEP PCR. Samples were genotyped by Sanger sequencing (Monot et al., 2009; Truman et al.,  
8 2011) or Whole Genome Sequencing (Benjak et al., 2018). Percentages of the samples positive for  
9 RLEP PCR and genotyped are shown.

10

11 **Figure 2. Phylogeography of *M. leprae* strains.** Maximum parsimony tree of 259 genomes of *M.*  
12 *leprae* built in MEGA 7. Support values were obtained by bootstrapping 500 replicates. Branch lengths  
13 are proportional to nucleotide substitutions. The tree is rooted using *M. lepromatosis*. The strains from  
14 Bangladesh are shown in red and their exact organization in the tree is shown in the two zoomed  
15 sections of the genotypes 1A-B and 1D. Strains with an A at SNP61425 in the *esxA* gene are shown in  
16 green. The specific 1B-Bangladesh genotype/cluster of Bangladesh strains is shown in blue.

17

18 **Figure 3. Distribution of *M. leprae* genotypes in Bangladesh.** Map of Bangladesh including markers  
19 indicating the residence of every subject with at least one sample genotyped for *M. leprae* (A), and  
20 zoomed into the area of interest (B). Each marker indicates an individual for whom *M. leprae* genotype  
21 was determined, either from slit skin smear, nasal swab or both samples. Genotype 1A is shown in  
22 green, 1B-Bangladesh in orange, 1D in blue, 1D-*esxA* in purple and 1\* in white. 1D-*esxA* is 1D subtype  
23 containing an A at SNP61425 in the *esxA* gene, formerly grouped as 1C (Monot et al., 2009; Truman et  
24 al., 2011). 1\* are samples with genotype 1 for which the subtype could not be determined. The figure  
25 was drawn in R (v3.4.3) with the package *leaflet* (v2.0.2) using maps from Esri – National Geographic

*M. leprae* genotypes in Bangladesh

5 **Figure 4. Correlation of IgM antibodies against PGL-I to Ct of RLEP qPCR.** Quantified levels of  
6 pathogen DNA (qPCR) and host immunity were correlated for samples selected for qPCR analysis  
7 based on RLEP positivity in multiple individuals in one household. Each dot represents a sample from  
8 one individual; leprosy patients are indicated in black, and healthy household contact in blue. Anti-  
9 PGL-I antibody levels were measured by up-converting reporter particles lateral flow assay specific for  
10 *M. leprae* PGL-I IgM antibodies ( $\alpha$ PGL-I UCP-LFA) using the Ratio (R) of the Test (T) and flow  
11 control (FC) lines as units. Ratios of  $\geq 0.10$  were considered positive as indicated by the red dashed  
12 line. RLEP cycle threshold (Ct) values are indicated on the x-axis and were measured by qPCR to  
13 detect *M. leprae* DNA in slit skin smears (SSS, left) and nasal swabs (NS, left). Undetermined Cts are  
14 depicted as Ct 40.
