Fecal microbiota transplantation in ulcerative colitis, a retrospective microbiome analysis

Marcel A. de Leeuw & Manuel X. Duval, GeneCreek

Background. Inflammatory bowel disease (IBD) is a set of conditions characterized by non-infectious chronic inflammation of the gastrointestinal tract. These primarily include Crohn's disease (CD), ulcerative colitis (UC) and indeterminate colitis. Fecal microbiota transplantation (FMT) has proven to be an effective treatment for some patients with active UC. However, factors contributing to the individual response to FMT therapy remain to be uncovered. There is currently no procedure allowing to predict the patients' response and to select the most adequate donor(s).

Methods. The first available UC longitudinal FMT microbiome data sets were reanalyzed, with focus on species level changes in the microbiota, using state-of-the-art and in part proprietary 16S analysis routines.

Results. We found the microbiomes of UC and CD patients to have paucity of obligate anaerobes, which could be a consequence of oxidative stress. Microbiomes of UC FMT responder donors have higher phylogenetic diversity and a higher proportion of facultative anaerobes as compared to non-responder donors. We found predicted antibiotic resistance to be higher in non-responders. We predicted succinate and histamine to be increased in non-responder donors and non-responders, respectively. Sialic acid catabolism was also predicted to be increased in non-responder donors. Tryptamine and indole-3-acetaldehyde were predicted to be increased in responder donors.

Implications. Our findings contribute to the establishment of selection criteria for UC FMT donor samples and composition guidelines for future synthetic microbial communities. Instead of replenishing missing obligate anaerobes, our results suggest that oxidative stress resistant facultative anearobes are important for the establishment of an anaerobic environment and a successful UC FMT therapy. Several metabolites can be tested for additional optimization or prioritization of stool bank samples for UC FMT. Our results question the relevance of antibiotics based preparation of the gut, prior to FMT.

Introduction

The incidence and prevalence of inflammatory bowel disease (IBD) are increasing worldwide. It can affect people of all ages, including children and geriatric populations, and can impact all aspects of life. The Global number of cases of IBD reached 6.8 million in 2017, with the highest age-standardized prevalence rates in the U.S.A. and the U.K. [1]. IBD is characterized by non-infectious chronic inflammation of the gastrointestinal tract, and primarily includes Crohn's disease (CD), ulcerative colitis (UC) and indeterminate colitis [2]. Whereas CD can affect any part of the gastroesophageal tract from the mouth to the anus, UC is confined to the large bowel. Diagnosis of IBD relies on a combination of medical history, physical examination, laboratory testing, and endoscopy with biopsy [3]. Treatment goals for IBD are to minimize symptoms, improve quality of life, and minimize progression and complications of the disease. Most treatments for UC target the immune system through mediators of the inflammatory cascade [4], but a substantial proportion of UC patients continue to have inadequate disease control.

Over 230 genetic risk loci have been associated with IBD. The association of the nucleotide-binding oligomerization domain containing protein 2 (NOD2), an intracellular innate immune sensor of bacteria, remains the strongest association to date [5]. The microbiota of UC patients are characterized by reduced complexity with depletion of commensal *Firmicutes* and *Bacteroidetes* [6–11], which is reflected in IgG antibody composition [12]. Mucosal concentration of bacteria is markedly increased in IBD [13], which is further accentuated in UC [14].

Fecal microbiota transplantation (FMT) is a therapeutic procedure aimed at replacing dysbiotic microbiota with physiological/commensal species by the administration of filtered fecal material from a healthy donor into the intestinal tract of a patient [15]. A number of studies, including randomized controlled trials [16–20], suggest that FMT is effective in the treatment of active UC, for approximately one out of three patients. It is as yet unclear which donor- and recipient related factors contribute to a successful clinical response, although in one study, donor stool diversity reached significance [17]. Current consensus guidelines focus on reducing the risk of potentially transmittable disease [21].

We combined a series of relevant longitudinal microbiome studies, available in the form of raw 16S data, in order to increase statistical power and to address elementary microbiome composition pertaining to clinical endpoints.

Materials & Methods

The materials summarized in Table 1 have been made available as part of clinical trials. All data sets are longitudinal, with data points covering pre-FMT assessment and post-FMT follow-up. Only one available data set, SRP254202, was eliminated entirely because of a high amount of non-specific priming. Biopsy samples from data set ERP116682 were eliminated because we detected high amounts of species reported as reagent contaminants [22]. For the purpose of profiling ulcerative colitis and Crohn's disease microbiomes, we also used the published data set listed in supplemental Table S1.

Data analysis

Amplicon Sequence Variants (ASVs) were generated with the R Bioconductor package dada2 [27], version 1.12.1 with recommended parameters, involving quality trimming, discarding of sequences with N's, assembly of forward and reverse sequences and chimera removal, as described previously [28]. Further analysis involved multiple alignment with mafft, version 6.603b [29] and approximately-maximum-likelihood phylogenetic tree generation with FastTreeMP, version 2.1.11 [30], both with default settings.

Taxonomic classification of ASVs was performed by an in-house Python and R program using random forest based supervised learning on the Ribosomal Database Project (RDP) release 11.5. Phenotypic content of microbiomes was inferred using species-level taxonomic assignments only and an in-house phenotypic database which has been initiated with information from BacDive [31] and the IJSEM journal [32] and has been hand-curated since. Resulting classifications and microbiome phenotypes are available from the Github repository https://github.com/GeneCreek/UC-manuscript in the form of Phyloseq R data objects.

UniFrac distances were computed using the R Bioconductor package phyloseq, version 1.28.0 [33] on raw ASVs. Further analysis used counts and relative abundances summarized at the species level, using the taxonomic classifications.

Detection of responder and non-responder associated taxa from a prevalence perspective was performed with χ^2 testing, with Monte Carlo simulation based computation of p-values [34].

Detection of responder and non-responder associated taxa from a relative abundance perspective was performed with the R package DESeq2, using negative binomial GLM fitting as described previously [28], requiring pAdj < 0.001.

Relative gene abundance prediction was performed using in-house R code, correcting for 16S copy numbers using the rrnDB version 5.4 [35] and using UniProt [36] provided per species non-redundant proteome counts and per species gene counts.

Downstream analysis scripts covering the figures presented in the manuscript are available from https://github.com/GeneCreek/UC-manuscript.

Results

Dysbiosis in IMIDs

Data set SRP183770 contains biological replicates of stool samples collected from patients with Crohn's disease (CD; N = 20), ulcerative colitis (UC; N = 19), multiple sclerosis (MS; N = 19), and rheumatoid arthritis (RA; N = 21) versus healthy controls (HC; N = 23) [37]. We initiated our study by describing the distribution of two fecal microbiome phenotypes, the species diversity with the Shannon diversity index and the strict anaerobes proportion, in UC samples within the context of these other immune mediated inflammatory diseases (IMIDs), Fig. 1. The strict anaerobes proportion is estimated as the proportion of obligate anaerobes among anaerobes. The ranking of the IMID's diseases is the same according to these two metrics, with notably rheumatoid arthritis positioned between ulcerative colitis and Crohn's disease.

Several publications have reported dysbiosis in UC can be reduced through FMT. This principle is illus-

Figure 1: Microbiome phenotypes in IMIDs. Data set SRP183770, 79 subjects, 201 samples. Numbers reflect Wilcoxon signed rank test continuity corrected p-values. HC: healthy controls, MS: multiple sclerosis, UC: ulcerative colitis, RA: rheumatoid arthritis, CD: Crohn's disease

trated using data set SRP108284 (20 patients) and Chao species richness in supplemental Fig. S1. The improvement reaches statistical significance in the samples collected in the second week after a single FMT, but washes out subsequently in the fourth week.

Just like species diversity, the strict anaerobe proportion can be modified through FMT, Fig. S2. The two donors used in study SRP198502 (7 patients) were selected based on fecal butyrate concentration [24] and had a high proportion of strict anaerobes.

Responder and non-responder patients

Combining the UC patients from all data sets for which responder/non-responder status was available in study metadata (ERP013257, SRP135559, ERP116682 and SRP102742 totaling 46 responders and non-responders to FMT and 159 samples), we tested several microbiome phenotypes in relation to the responder status, two of which reached significance, Fig. 2. Responders have a lower predicted average biological safety level (BSL) and a predicted more gram positive microbiome.

Figure 2: Predicted phenotypic differences between responder and non-responder microbiomes. Combined data sets ERP013257, SRP135559, ERP116682 and SRP102742, 46 patients, 159 samples. BSL: predicted average biological safety level of the microbiome. NR: non-responders, RE: responders. Numbers reflect Wilcoxon signed rank test continuity corrected p-values.

In data set ERP013257 [17] the predicted average BSL of the microbiome is significantly different between non-responders, partial responders and responders, Fig. S3. In the experience, an antibiotics course was used prior to FMT. In non-responders and partial responders, there was a spike in BSL after the 10-day antibiotics course, whereas in responders, this phenomenon was not seen. Subsequently, after FMT, the BSL remained lower in responders, Fig. 3.

We also computed both prevalence and relative abundance differences between non-responders and responders using the four responder/non-responder data sets combined, Table S2 respectively S3 and S4. We found *Allisonella histaminiformans* to be the most sig-

nificantly prevalent in non-responders.

Figure 3: BSL trajectory across antibiotics course, FMT and follow-up. Data set ERP013257, 13 patients. Data points reflect the median predicted biological safety levels per response group. NR: non-responders, PR: partial responders, RE: responders. Antibiotics course: days -10 to 0, FMT: day 1.

Responder and non-responder donors

Data set ERP013257 comprises 51 samples from 12 donors which are associated with either non-response, partial response or response to UC treatment with FMT [17]. Multi-dimensional scaling ordination separates responders- and non-responder donors, with partial responder donors in an intermediate position, Fig. S4. We tested several microbiome phenotypes, in relation to the responder donor status. Phylogenetic diversity and predicted average oxygen tolerance reached significance, Fig. 4.

Figure 4: Donor microbiome phenotypes, data set ERP013257. 51 samples from 12 donors. Numbers reflect Wilcoxon signed rank test continuity corrected p-values. Donors are associated with NR: non-responders, PR: partial responders, RE: responders.

We also computed both prevalence and relative abundance differences between non-responder and responder donors using data set ERP013257, Table S5 respectively S6. We found very little overlap between donor- and patient responders or non-responders.

Functional differences between responder and non-responder microbiomes

The following metabolites in relation to UC were the subject of queries to the UniProtKB section of UniProt: succinate, glutathione, tryptophan and sialic acid. Queries provided in Table S7 gave rise to significant differences between responder and non-responder microbiomes or between responder and non-responder donor microbiomes as appreciated by Tukey honest significant difference testing, Table 2.

Succinate is a metabolic intermediate of the tricarboxylic acid (TCA) cycle. Succinate is also produced in large amounts during bacterial fermentation of dietary fiber. Fecal succinate concentrations are approximately three to four-fold higher in IBD patients compared to controls [38]. When projecting relative gene abundance, we found succinate producing fumarate reductase and succinate-semialdehyde dehydrogenase associated with non-responder donors.

Glutathione (GSH) is one of the most potent natural antioxidants and found mostly in Gram-negative bacteria [39]. GSH metabolism involves several genes including catabolism (amino-acid uptake), synthesis and

use for redox control. Projecting relative gene abundance, we found several genes were predicted to be differentially abundant between responder- and non-responder donors. Synthesis and use for redox control were associated with responder donors and uptake was associated with non-responder donors. When comparing predicted gene copy numbers in patient microbiomes, one additional catabolic gene, ggt, was found associated with non-responders.

Tryptophan metabolism has been found associated with IBD activity, with possible implication of gut microbiota [40]. We found three tryptophan metabolism genes, one uptake and two catabolic genes predicted to be increased in non-responder patients, Table 2. We found the first catabolic gene, kynU in association with non-responder donors, but paradoxically the second catabolic gene, araT, in association with responder donors.

Sialic acid is an abundant and the most terminally expressed carbohydrate on mucus glycans. Bacterial metabolism of sialic acid comprises scavenging, catabolism, synthesis and decoration [41]. Projecting relative gene abundance, we found several genes are predicted to be differentially abundant between responder- and non-responder donors. Catabolism was found associated with non-responder donors and synthesis with responder donors.

Discussion

Limitations. The majority of the data sets used in this study are from 16S variable region V4 sequencing. A substantial number of species cannot be resolved using this amplicon. A better alternative is the combined V3-V4 amplicon which can be sequenced using the same technology, with paired-end reads.

Oxidative stress in UC. Oxidative stress has been proposed as a mechanism underlying the pathophysiology of CD [42] and has long been known as a pathogenic factor of UC [43]. If radical oxygen species (ROS) are released in the lumen, we may expect modulation of the microbiome composition. Indeed, we observe a decreased proportion of strict anaerobes in the microbiome composition of UC and CD samples, accompanied by loss of species diversity. The loss of obligate anaerobes in IBD has been reported previously [44]. Thus we postulate oxidative stress in IMIDs drives the decrease in obligate anaerobes, which results in the loss of microbial diversity and loss of function such as butyrate production.

Not withstanding the above, we found responder donor samples had higher phylogenetic diversity and higher predicted oxygen tolerance as compared to non-responder donors. Thus rather than directly supplying missing strict anaerobes, provision of facultative anaerobes capable of restoring an anaerobic environment seems important for successful UC FMT.

Antibiotics based gut preparation. We found a remarkable association between predicted microbiome BSL, i.e. antibiotic resistance and non-responder/responder status, with responder microbiomes having a lower predicted BSL. This finding highlight the controversial role of broad-spectrum antibiotics based preparation of the gut prior to FMT [45], if applied. The positive selection of resistant species seems to have a detrimental effect on FMT success. It appears from our findings that antibiotics based cleansing in the specific context of UC in addition to conventional bowel cleaning solution used for colonoscopy preparation needs to be questioned.

Metabolites and UC. Increased intestinal succinate levels have been reported in the well-known Dextran Sulfate Sodium (DSS) induced mouse colitis model and proposed as a causative agent [46]. In humans, fecal succinate concentrations are approximately three to four-fold higher in IBD patients compared to controls [38]. We found predicted relative gene abundance of two succinate producing enzymes increased in non-responder donors.

Mucosal histamine has been reported to reflect the degree of colonic inflammation in Crohn's disease and ulcerative colitis [47]. Furthermore, the His645Asp polymorphism of the histamine metabolizing enzyme ABP1 is related to severity of ulcerative colitis [48]. We found *Allisonella histaminiformans* to be the most differentially prevalent species in non-responders. We also find histamine forming histidine decarboxylase (hdc, ec: 4.1.1.22) carriers such as *Clostridium perfringens*, *Lactobacillus reuteri*, *Proteus vulgaris* and *Morganella morganii* among non-responder associated species. Reportedly, *Enterobacter cloaceae* and *Proteus mirabilis* are also histamine producers [49]. We found both associated with non-responders too. Histidine decarboxylase did, however, not reach significance in our differential predicted relative gene abundance test.

Decreased serum levels of tryptophan are correlated with disease activity in IBD [40]. Tryptophan synthesis is a virulence factor of bacterial pathogens, allowing for survival in macrophages. We found tryptophan synthase A to be predicted increased in non-responder donors. It is more intricate to interpret predictions regarding the metabolite indole-3-pyruvic acid (IPA), which we find associated with non-responders but also with responder donors. The latter is coherent with the fact that IPA is diminished in circulating serum from human subjects with active colitis [50]. One possible explanation lies in species specific substrate preferences of aromatic amino acid transaminase, which is potentially also active on tyrosine and phenylalanine. Lastly, we found two catabolic genes associated with responder donors, padI and aofH, respectively and successively producing tryptamine and indole-3-acetaldehyde (IAAld), both aryl hydrocarbon receptor (AhR) ligands contributing to AhR-dependent IL-22 transcription [51]. AhR ligands have also been shown to regulate the IL-10 receptor [50]. Thus these products contribute to intestinal homeostasis.

Mucosal barrier function. Sialic acid is an abundant and the most terminally expressed carbohydrate on mucus glycans. Removal of sialic acid is the first overall step in microbial infiltration of the mucus layer. Exosialidases have been shown to increase availability of nutrients for *Escherichia coli* expansion in the DSS induced mouse colitis model [52]. We found predicted sialic acid uptake and catabolism but not scavenging in strong association with non-responder donors. The various *Bacteroides* species, *Akkermansia muciniphyla* and *Feacilibacterium prausnitzii* carrying the scavenger gene nanH were found equally present in responder- and non-responder patients and donors.

Prospects

Our findings can be used to rationalize selection of donor samples from stool banks. Transplantation of facultative anaerobes can be enhanced with culture conditions. From a metabolic standpoint, low succinate and histamine levels should be preferred, whereas higher tryptamine and IAAld levels would be a plus. Sialic acid catabolism could be addressed through qPCR of key catabolic enzymes encoding genes such as nanH and nanA, of which lower levels would reduce over-colonization of the mucus barrier. Our results suggest that in the specific context of UC FMT, broad-spectrum

antibiotics based preparation of the gut needs to be compared in a randomized clinical trial against solution based cleansing only.

Conclusions

In conclusion, we found the microbiomes of UC and CD patients to have paucity of obligate anaerobes, which could be related to oxidative stress. Microbiomes of UC FMT responders and responder donors have higher phylogenetic diversity and a higher proportion of facultative anaerobes as compared to non-responders and non-responder donors. We found several predicted metabolites associated with either non-responder status or responder status of patients and donors. We also found predicted sialic acid catabolism to be significantly associated with non-responder donor status. These findings should contribute to the establishment of selection criteria for UC FMT donor samples and composition guidelines for future synthetic microbial communities.
