9 **Abstract**

10 Effective public health response to viral outbreaks such as SARS-CoV-2 require reliable information about
11 the spread of the infecting agent. Often real-time PCR screening of large populations is a feasible method
12 to generate this information. Since test capacities are usually limited, pooling of test specimens is often
13 necessary to increase screening capacity, provided that the test sensitivity is not significantly compromised.
14 However, when a traditional pool is tested positive, all samples in the pool need individual retesting, which
15 becomes ineffective at a higher proportion of positive samples. Here, we report a new pooling protocol
16 that mitigates this problem by replicating samples across multiple pools. The resulting pool set allows the
17 sample status to be resolved more often than with traditional pooling. At 2% prevalence and 20 samples
18 per pool, our protocol increases screening capacity by factors of 5 and 2 compared to individual testing
19 and traditional pooling, respectively. The corresponding software to layout and resolve samples is freely
20 available under a BSD license (<https://github.com/phiweger/clonpool>).

21 Main text

22 Pooling of test specimen has long been used to screen larger collections of samples, when most of them
23 are expected to test negative.¹ In outbreak situations such as the current SARS-CoV-2 pandemic, this
24 “pooling” allows screening of large populations to guide public health response. However, in most labora-
25 tories, the screening capacity is limited by the number of PCR reactions that can be performed in a given
26 time. It is, therefore, desirable to maximize the number of samples that can be tested per reaction.

27 Various approaches have been proposed to do so in the context of SARS-CoV-2 RT-PCR testing.^{2,3} One
28 problem with the traditional pooling approach, where several samples are collected and tested collectively,
29 is that the number of positive pools that require individual retesting increases rapidly with the number
30 of positive samples in the overall population. A high prevalence of the target renders traditional pooling
31 ineffective. To mitigate this, we propose to test specimens in replicates and distribute them across multiple
32 pools. The resulting “pool address” can then be used to resolve samples in one pool, given the information
33 from other pools that contain a replicate. While some previous studies have taken a similar approach
34 implicitly,² it has neither been investigated systematically for more replicates than two, nor is there any
35 software that would generate and resolve the corresponding pooling layout for laboratory use.

36 We therefore introduce “clonepool”, a pooling framework to maximize the effective number of samples s_e
37 per PCR reaction. “Effective” refers to the fact that samples in positive pools, whose status cannot be
38 resolved in the pooled run, are assumed to be retested individually. The maximum number of samples for
39 a given pool size p , number of pools n and number of replicates r is calculated as $s_m = \frac{pn}{r}$. The effective
40 number of samples can then be calculated from the number of unresolved samples s as $s_e = \frac{s_m}{p+s}$.

41 The clonepool algorithm first distributes all sample replicates randomly across the available pools, with
42 the limitation that a sample’s replicates do not co-occur in the same pool. After the pools have been
43 tested, the algorithm attempts to resolve the samples’ status in two phases: In a first phase, all samples
44 that have at least one replicate in a negative pool are marked negative. In the second phase, samples that
45 (a) only occur in positive pools, and (b) have at least one replicate in a pool in which all other samples
46 are known to be negative, are marked positive (red, orange). All other samples cannot be resolved, and
47 need to be retested individually. The longer the set of pools a sample is distributed across, i.e., the larger
48 its pool set, the more samples can be resolved given a particular prevalence. Of course, a higher number
49 of replicates comes at the price of a reduced number of samples which can be processed at a fixed number

50 of wells. Fortunately, our results provide an efficient means to find the optimal trade-off for any given set
51 of parameters.

Figure 1: Illustration of the clonepool algorithm. Circles denote the wells, each containing a pool of samples (small squares). A distinct color marks all replicates of a single sample. Positive samples are flagged with “+”, negative ones remain empty. Positive pools are shaded in grey, negative ones in white. In a first phase, all samples that have at least one replicate in a negative pool are identified as negative (blue, green). In the second phase, samples that only occur in positive pools and where at least one replicate is in a pool where all other samples are negative, are recognized as positive (red, orange). All other samples cannot be resolved and have to be retested individually (yellow).

52 We tested the proposed clonepool algorithm using simulated data. We assumed no pipetting errors,
53 which can be achieved, e.g., through the use of a pipetting robot. We also assume that 94 pools are
54 available, which corresponds to a 96-well plate with two wells reserved for a positive and a negative
55 control. Furthermore, we assume that there are no false positive or false negative PCR reactions.

56 Two parameters determine which pooling scheme is most effective (Fig. 2). If both the prevalence and
57 the number of samples per pool are low, traditional pooling without replicates yields the highest number
58 of samples per reaction. However, as the prevalence increases or more and more samples are pooled,
59 the number of positive pools increases, causing a large number of retested samples and thus reducing the
60 overall throughput. Using sample replicates will then allow to resolve more samples than in the traditional
61 approach. In our testing experience, we observed a prevalence of about 5%, but this value is subject to
62 variability, e.g., depending on a population’s pre-test probability.

63 The number of samples that can be pooled without affecting the PCR sensitivity is limited by the PCR
64 cycle threshold (Ct) for the target, i.e., the cycle at which amplification becomes detectable over back-
65 ground noise (typically ten times the standard deviation, SD). Usually, Ct values above 35 are treated
66 as unspecific amplification. SARS-CoV-2 amplifies at low Ct values due to high viral titers (Ct 18-25
67 depending on the material and number of days post-infection).^{4,5} A 20-fold dilution, i.e., pooling 20 sam-
68 ples, would cause the Ct value to increase by about 4.3 cycles ($2^x = d$, where d is the dilution and x the

69 shift in Ct), which still lies comfortably above the detection limit.

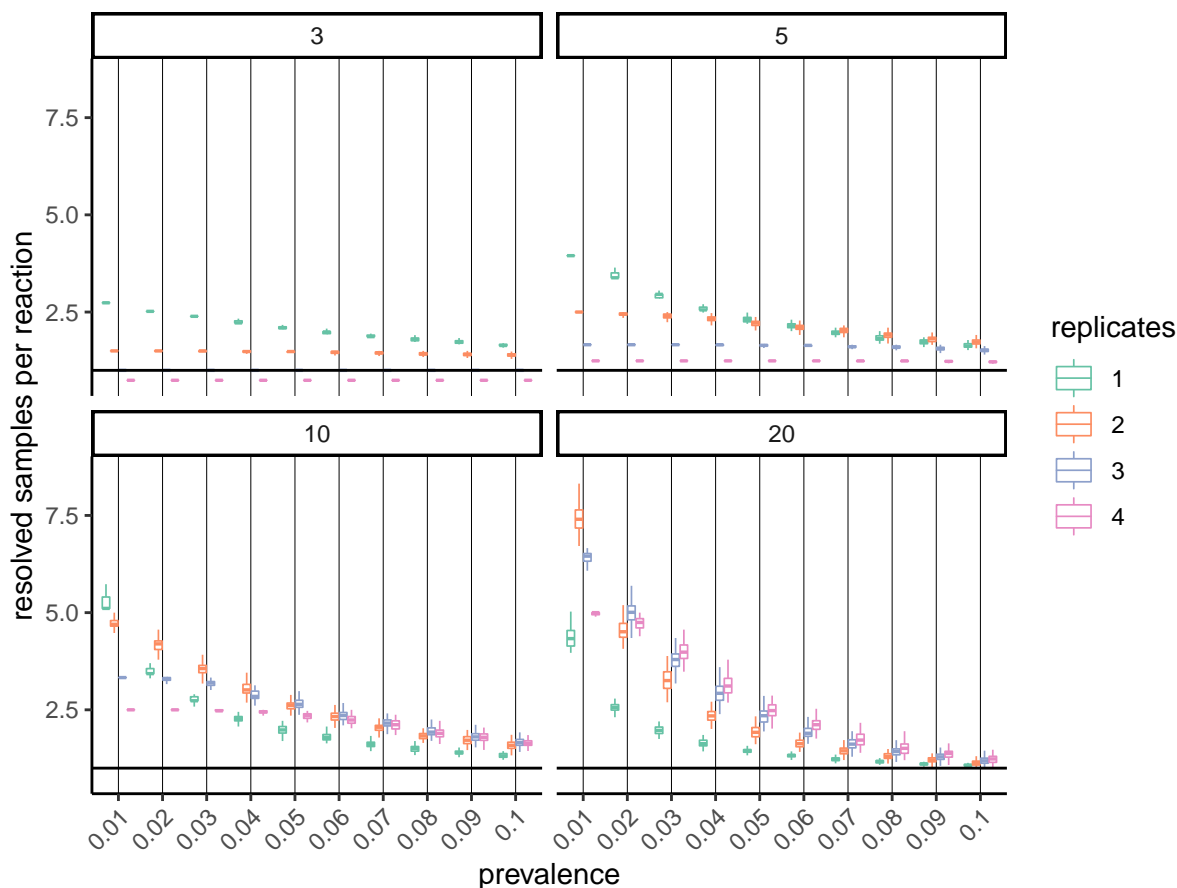

Figure 2: Simulation results for different percentages of positive samples (x-axis), replicates (colors), and pool sizes (panels). The target metric is the effective number of samples per PCR reaction, which includes the individual retesting of samples that cannot be resolved in the first pooling run.

70 At a prevalence of 5% SARS-CoV-2 positive samples, and for ten samples per pool and two replicates per
71 sample, we simulate that 2.61 times the number of samples can be processed compared to testing samples
72 individually (SD 0.13). This result is in line with previous estimates using a slightly different version of
73 the 2-replicate scheme.² Using two replicates increases the effective number of samples per reaction by
74 31% compared to pooling without replicates. At 2% prevalence and 20 samples per pool – a scenario
75 more akin to screening large populations – 5.01 times the number of samples can be screened compared
76 to individual testing (SD 0.28), and the increase over traditional pooling is 193%. These presented values
77 correspond to *in silico* simulations, and require further validation in the laboratory.

78 In conclusion, our pooling protocol based on sample replicates can substantially increase the number of
79 samples per PCR reaction when screening large populations during pathogen outbreaks, such as SARS-

80 CoV-2. The protocol can be tuned to local laboratory conditions such as pool size and proportion of
81 positive samples. Also, subsequent testing of positive pools could be made more efficient by splitting
82 pools iteratively.⁶

83 The clonpool software supports the protocol's implementation for routine use ([https://github.com/](https://github.com/phiweger/clonpool)
