Abstract

Against the current COVID-19 pandemic, governments worldwide have devised a variety of non-pharmaceutical interventions to suppress it, but the efficacy of distinct measures is not yet well quantified. In this paper, we propose a novel tool to achieve this quantification. In fact, this paper develops a new extended epidemic SEIR model, informed by a socio-political classification of different interventions, to assess the value of several suppression approaches. First, we inquire the conceptual effect of suppression parameters on the infection curve. Then, we illustrate the potential of our model on data from a number of countries, to perform cross-country comparisons. This gives information on the best synergies of interventions to control epidemic outbreaks while minimising impact on socio-economic needs. For instance, our results suggest that, while rapid and strong lock-down is an effective pandemic suppression measure, a combination of social distancing and contact tracing can achieve similar suppression synergistically. This quantitative understanding will support the establishment of mid- and long-term interventions, to prepare containment strategies against further outbreaks. This paper also provides an online tool that allows researchers and decision makers to interactively simulate diverse scenarios with our model.

Keywords

COVID-19, Cross-country comparison, Risk assessment, Epidemiological modelling, Non-pharmaceutical interventions, Public health.

1 Introduction

The current global COVID-19 epidemic has led to significant impairments of public life world-wide. To suppress the spread of the virus and to prevent dramatic situations in the healthcare systems, many countries have implemented a combination of rigorous measures like lock-down, isolation of symptomatic cases and the tracing, testing, and quarantine of their contacts. In order to gain information about the efficacy of such measures, a quantitative understanding of their impact is necessary. This can be based on statistical methods [1] and on epidemiological models [2]. While statistical methods allow for accurate characterization of the population's health state, epidemiological modeling can provide more detailed mechanisms for the epidemic dynamics and allow investigating how epidemics will develop under different assumptions.

NOTE: This preprint reports new research that has not been certified by peer review and should not be used to guide clinical practice.

11 Preliminary efforts have been made to quantify the contribution of different policy interventions [3],
12 but these rely on complex models based on a number of assumptions. We base our study on a clas-
13 sical SEIR-like epidemiological model. SEIR models are minimal mechanistic models that consider
14 individuals transitioning through Susceptible \rightarrow Exposed \rightarrow Infectious \rightarrow Removed state during the
15 epidemics [4]. The essential control parameter is the basic reproduction number R_0 [5], that worldwide
16 non-pharmaceutical suppression strategies aim at reducing below the threshold value 1. Building on
17 this, we incorporate additional compartments reflecting different categories of intervention strategies,
18 identified by socio-political studies [6]. In particular, the model focuses on three main suppression pro-
19 grams: social distancing (lowering the rate of social contacts), active protection (decreasing the number
20 of susceptible people), and active removal of latent asymptomatic carriers [7]. This study investigates
21 how these programs achieve repression both individually and combined, first conceptually and then
22 by cross-country comparison. This information can supply Government decisions, helping to avoid
23 overloading the healthcare system and to minimise stressing the economic system (due to prolonged
24 lock-down). We expect our model, together with its interactive online tool, to contribute to crucial tasks
25 of decision making and to prepare containment strategies against further outbreaks.
26

27 **2 Methods**

28 This study links policy measures to epidemiological modelling and uses the developed model to quan-
29 titatively assess the efficacy of different interventions in six countries. In this section, we illustrate the
30 modelling choice and the use of data.

31 **2.1 The classical SEIR model**

32 SEIR models are continuous-time, mass conservative compartment-based models of infectious diseases
33 [4, 8]. They assume homogeneous propagation media (or fully connected graphs) and focus on the evo-
34 lution of mean properties of the closed system. All of these models, from the more conceptual to more
35 realistic versions, e.g. SEIR with delay [9], spatial coupling [10], or individual-based models [11], are
36 classical and widely used tools to investigate the principal mechanisms governing the spread of infec-
37 tions and their dynamics.

38 Main compartments of SEIR models (see Fig. 1, framed) are: susceptible S (the pool of individuals likely
39 to be infected), exposed E (corresponding to latent carriers of the infection), infectious I (individuals
40 having developed the disease and being contagious) and removed R (those that have processed the dis-
41 ease, being either recovered or dead). The model's default parameters are the average contact rate β ,
42 the inverse of mean incubation period α and the inverse of mean contagious period γ . When focusing
43 on infection dynamics rather than patients' fate, the latter combines recovery and death rate [12]. From
44 these parameters, epidemiologists calculate the "basic reproduction number" $R_0 = \beta/\gamma$ [13] at the epi-
45 demic beginning. During the epidemic progression, isolation after diagnosis, vaccination campaigns
46 and active suppression measures are in action. Hence, we speak of "effective reproduction number"
47 $\hat{R}(T)$ [14].

48 **2.2 Data and analyzed countries**

49 Governments worldwide have issued a number of social measures, including those for public health
50 safeguard, economic support, movement restriction and non-pharmaceutical interventions to hamper
51 disease spreading. Scholars from political sciences and sociology have recorded and classified such mea-
52 sures [15, 16]. Among the resources listed on the World Health Organization "Tracking Public Health
53 and Policy Measures" [6], we used information from the ACAPS database [17] that contains a curated
54 categorization of policy measures. ACAPS is an independent, non-profit information provider helping
55 humanitarian actors respond more effectively to disasters. The ACAPS analysis team has aggregated
56 and classified interventions from different sources (media, governments and international organiza-
57 tions), for all countries and in time. Suppression measures against the epidemic are classified under
58 "Movement restrictions", "Lock-down", "Social Distancing" and "Monitoring and Surveillance". Our

Country	Measures	Param. involved	Starting Date	Population (rounded)
Austria (AT)	Partial lock-down	μ, ρ	16 Mar	9,000,000
	Social distancing	ρ, μ	16 Mar	
	Contact tracing	χ	16 Mar	
Denmark (DK)	Phase-out		Around 14 April	6,000,000
	Social distancing	ρ, μ	13 Mar	
	Mild surveillance	χ	13 Mar	
Ireland (IR)	Phase-out		14 Apr	5,000,000
	Partial lock-down	μ, ρ	28 Mar	
	Social distancing	ρ, μ	13 Mar	
Israel (IL)	Phase-out		18 May	9,000,000
	Partial lock-down	μ, ρ	15 Mar	
	Social distancing	ρ, μ	15 Mar	
Lombardy (LO)	Contact tracing	χ	15 Mar	10,000,000
	Phase-out		19 April	
	Lock-down	μ, ρ	13 Mar (Italian)	
Switzerland (CH)	Social distancing	ρ, μ	13 Mar	8,500,000
	Phase-out		Around 15 Apr	
	Lock-down.	μ, ρ	16 Mar	
	Social distancing	ρ, μ	16 Mar	
	Phase-out		27 Apr	

Table 1: Test countries, with measures implemented (following the ACAPS database [17]), corresponding parameter in our SPQEIR model and starting date. For Lombardy, we used the Italian official date for lock-down. Differently from other countries, Ireland issued measures on two different dates; we use this case to compare social distancing and lock-down effect in a single country. We also report the (rounded) population of each country.

59 modelling choice is based on these categories, which are reflected by additional compartments to the
60 classical SEIR model (see next section).

61
62 Epidemiological data for all selected countries and regions were obtained from the COVID-19 Data
63 Repository by the Center for Systems Science and Engineering (CSSE) at Johns Hopkins University [18].
64 The data are from 22 Jan 2020 to 08 July 2020. Lombardy data were obtained from the Protezione Civile
65 Italiana data repository “Dati COVID-19 Italia” [19], from 22 Feb 2020 to 08 July 2020.

66
67 This study analyses the effect of suppression measures in flattening the curve. Despite having a
68 precise starting date, such measures take some days to be fully effective. We estimate an average delay
69 using the Google Mobility Reports [20, 21] for the selected countries. Google provides changes in mo-
70 bility with respect to a monthly baseline, w.r.t. 6 locations: Retail & Recreation, Grocery & Pharmacy,
71 Transit stations, Workplaces, Residential, Parks. We average the decrease in mobility at the first four
72 locations (corresponding to those where social mixing happens more frequently [22]) to get a proxy of
73 the time needed for hard lock-down to be fully effective (cf. Fig. 4c).

74 2.3 The extended SPQEIR model to reflect suppression strategies

75 SEIR models reproduce the typical bell-shaped epidemic curves for the number of infected (and still
76 infectious) people. These quantify the main stressors for both the health system, i.e. the peak of the
77 curve, and the economic system, i.e. the time \mathbb{T} passed until no new infections occur. Mainstream
78 suppression measures against the epidemic aim at flattening the curve of new infections [7]. However,
79 the classical SEIR model is not granular enough to investigate suppression measures when they need to
80 be considered or should be sequentially reduced if already in place. Therefore, we extend the classical
81 SEIR model as in Fig. 1 (red insertions) into the SPQEIR model, to reflect the intervention categories
82 described above. The model can be summarized as follows:

- 83 • The classical blocks S, E, I, R are maintained;
- 84 • A social distancing parameter ρ is included to tune the contact rate β ;
- 85 • Two new compartments are introduced where:
- 86 – Protected P includes individuals that are isolated from the virus through lock-down, thus
- 87 reducing the susceptible pool ;
- 88 – Quarantined Q describes latent carriers that are identified and quarantined after monitoring
- 89 and tracing.

90 We do not introduce a second quarantined state for isolation of confirmed cases after the Infectious

91 state [23, 2] but consider this together with the Removed state (see Liu et al. [24] and references therein).

92 Quarantining infected symptomatic patients is a necessary first step in every epidemic [25]. An addi-

93 tional link from Q to R, even though realistic, is neglected as both compartments are already outside the

94 “contagion system” and would therefore be redundant from the perspective of evolution of the infec-

95 tion. In general, protected individuals can get back to the pool of susceptible after a while, but here we

96 neglect this transition, to focus on simulating repression programs alone. Long-term predictions could

97 be modelled even more realistically by considering such link, that would lead to an additional parame-

98 ter to be estimated and is beyond the scope of the present paper.

99

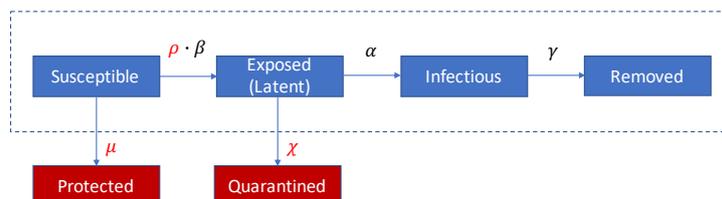

Fig. 1 Scheme of the SPQEIR model. The basic SEIR model (framed blue blocks) is extended by the red blocks to the SPQEIR model. Parameters that are linked to repression strategies are shown in red. Interpretation and values of parameters are given in Table 2.

The model has in total 6 parameters. Three of them (β, α, γ introduced in Fig. 1) are based on the classical SEIR model. The new parameters ρ, μ, χ account for alternative repression programs (see Table 2 for details). Commonly, social distancing is modeled by the parameter ρ . It tunes the contact rate parameter β , resulting in the effective reproduction number $\hat{R} = \rho \cdot \beta \gamma^{-1}$. This occurs in a closed-system setting where all individuals belong to the susceptible pool, but interact less intensively with each other. The parameter μ stably decreases the susceptible population by introducing an active protection rate. This accounts for improvements of public health, e.g. stricter lock-down of communities, or physical reduction of a country’s population like reduced commuters’ activity. This changes the effective reproduction number into $\hat{R} = \beta \gamma^{-1} (1 - \mu)^T$ with T being the number of days the measures are effective [26]. The parameter χ introduces an active removal rate of latent carriers. Intensive contact tracing and improved methods to detect asymptomatic latent carriers may enhance the removal of exposed subjects from the infectious network. Following earlier works [27, 28] and adjusting the current parameters, \hat{R} can be then expressed as $\hat{R} = \beta \gamma^{-1} \alpha (\alpha + \chi)^{-1}$. Parameter values that are not related to suppression strategies are set from COVID-19 epidemic literature [24, 29]. We use mean values as the main focus of the present model lies on sensitivity analysis of suppression parameters. Our model can be further extended by time dependent parameters [25]. Default values for suppression parameters are $\{\rho, \mu, \chi\} = \{1, 0, 0\}$, corresponding to the classical SEIR model.

The dynamics of our SPQEIR model is described by the following system of differential equations:

$$\begin{aligned}\dot{S} &= -\frac{\rho\beta SI}{N} - \mu S, \\ \dot{E} &= \frac{\rho\beta SI}{N} - (\chi + \alpha) E, \\ \dot{I} &= \alpha E - \gamma I, \\ \dot{R} &= \gamma I, \\ \dot{P} &= \mu S, \\ \dot{Q} &= \chi E,\end{aligned}$$

with conservation of the total number of individuals, meaning $\dot{N} = 0$ with $N = S + E + I + R + P + Q$. As a value for the qualitative study, we used $N = 10,000$. For the cross-country assessment, N is adjusted to true population values for each country. Overall, the effective reproductive number becomes

$$\hat{R} = \frac{\rho\beta}{\gamma} \frac{\alpha}{\alpha + \chi} (1 - \mu)^T, \quad (1)$$

100 with T being the number of days that the measures leading to compartment P are active.
101 Suppression measures are initiated several days after the first infection case. Hence, we activate non-
102 default parameter values after a delay τ . In conceptual simulations, we set it arbitrarily without loss
103 of generality. For data fitting, we fit and compare it to the official date when measures are initialized
104 (cf. Table 1). To integrate the model numerically, we use the *odeint* function from *scipy.integrate* Python
105 library.
106

Fixed parameters	Suppression parameters
$\beta = (\text{average contact rate in the population}) = 0.85 \text{ d}^{-1}$	$\mu = (\text{rate of active protection}) [d^{-1}]$
$\alpha = (\text{mean incubation period})^{-1} = 0.2 \text{ d}^{-1}$	$\rho = (\text{social distancing tuning})$
$\gamma = (\text{mean infectious period})^{-1} = 0.34 \text{ d}^{-1}$	$\chi = (\text{active removal rate}) [d^{-1}]$
$R_0 = 2.5$	

Table 2: SPQEIR model parameters with their standard values for the COVID-19 pandemic from literature [24, 30]. Here “ d ” stands for days.

107 2.4 Model fitting

We fit the model to the official number of currently infected (active) cases, for each considered country. Model fitting to the infectious curves is performed in two steps, using the parameters known to be active (cf. Table 1). First, we estimate the “model consistent” date of first infection, so that the simulated curve matches the reported data of active infections. This initial step corresponds to setting the time initial conditions of the SEIR model [2, 26]. The fitting is performed with default parameter values, on a subset of data corresponding to the first outbreak, from first case until when measures are implemented (cf. Table 1). We use a grid search method for least squares, sufficient to fit a single parameter:

$$t_0 = \left\{ t' \mid RMS = \min_{t'} \sqrt{\frac{\sum_{i=t'}^{t_m} (x(i) - \hat{x}(i))^2}{n}} \right\} \quad (2)$$

108 where t_0 is the “model consistent” estimated date of first infection, t_m refers to the date measures are
109 implemented, \hat{x} and x are respectively reported and model-predicted data, and n is the number of points
110 between t and t_m .
111

112 The second step estimates the suppression parameters that yield the best fitting of the simulated
113 SPQEIR curve on reported data, during the first phase with implemented measures. This period is iden-
114 tified between the starting date t_m (also included in the fitting) and the phase-out date t_p , cf. Table
115 1. Holding the epidemic parameters to literature values to achieve cross-country comparison on inter-
116 vention parameters alone, the fitting is performed for a set of suppression parameters relative to each
117 country, as reported by policy databases (cf. Table 1). The fit is performed with *lmfit* Python library.

118
When more parameters are involved at once, we also perform a comparative information analysis
between our extended model and the simplest SEIR that lumps parameters under a single “social dis-
tancing” ρ . This shows what we gain in distinguishing the intervention parameters, not only in terms of
improved interpretation, but also in terms of model fitting. We employ a reduced χ^2 metric to evaluate
the goodness-of-fit for both models, considering the degrees of freedom [31]:

$$\chi_{red}^2 = \frac{1}{n' - 1 - k} \sum_{j=1}^{n'} \frac{(y_j - \hat{y}_j)^2}{\hat{y}_j} \quad (3)$$

119 where n' is the number of data points until phase-out, k is the number of parameters in the model, y_j
120 are estimated values and \hat{y}_j the expected ones. The lower the χ_{red}^2 value, the better the SPQEIR model
121 fits the data w.r.t. the simplest “social distancing” SEIR model.

122 3 Results

123 We first focus on the conceptual analysis of the effect of suppression interventions, initially for single
124 measures (social distancing, active protection and active quarantining) and subsequently for a number
125 of synergistic approaches. In particular, we study how crucial quantities, namely the infectious peak
126 height and time to zero infectious, depend on suppression parameters and affect \hat{R} . We define \mathbb{T} as the
127 time when there are less than 0.5 individuals in the I compartment. This because ODE models approx-
128 imate discrete quantities with continuous variables. Finally, we perform model fitting and intervention
129 assessment over a set of countries. This provides quantitative outputs about the effectiveness of real
130 measures, informing about the synergies applied and enabling cross comparison.

131 3.1 Mathematical analysis of single suppression measures

132 3.1.1 Only social distancing

133 The parameter ρ captures social distancing effects, taking values in the interval $[0, 1]$, where 0 indicates
134 no contacts among individuals while 1 is equivalent to no actions taken. Without loss of generality,
135 simulations consider a delay of 10 days from the first infection to the time social distancing is initiated.
136 Fig. 2 reports simulation results. The curve of infectious is progressively flattened by social distancing
137 (2a) and its peak suppressed (2b). However, the eradication time gets delayed for decreasing ρ , until
138 a threshold yielding a disease-free equilibrium rapidly (2c). In this case, the critical value for ρ is 0.4,
139 leading to $\hat{R} < 1$. However, we notice that values of $\rho \simeq 0.3$ or lower are more effective in suppressing
140 the epidemic faster. This is in line with early findings, suggesting that epidemic control with social
141 distancing alone should be done “well or not at all” [32].

142 3.1.2 Only active protection

143 As above, our simulations take into account 10 days delay from the first infection to the initiation of
144 active protection. The range of μ is only up to values similar to those measured in China [26]. Higher
145 values are considered for step-wise hard lock-down (see below). The results are reported in Fig. 3. We
146 see that small precautions can make an initial difference, but then the effects saturate (Fig. 3a,b). The
147 time to zero infectious is decreased with higher values of active protection (Fig. 3a,b). In particular,
148 $\mu = 0.01 d^{-1}$ suppresses the epidemics in about 6 months by protecting 70% of the population. Higher
149 values of μ achieve suppression faster, while protecting almost 100% of the population. If protection is

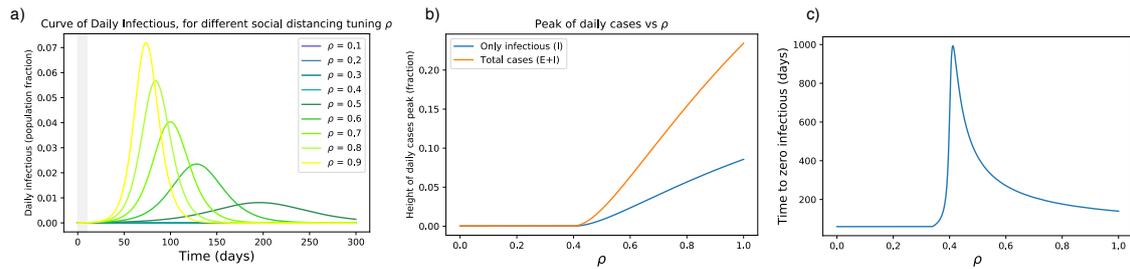

Fig. 2 (a) Effects of social distancing on the epidemic curve. The grey area indicates when measures are not yet in place. (b) The peak is progressively flattened until a suppression is reached for sufficiently small ρ . For these settings, the critical value for ρ is 0.4 (it pushes \hat{R} below 1). (c) Unless ρ is small enough, stronger measures of this kind might delay the suppression time \mathbb{T} of the epidemic.

150 mostly achieved through isolation, this is unrealistic. However, this models effective vaccination strate-
151 gies.

152
153 We also consider hard lock-down strategies which isolate many people at once [33]. This corresponds
154 to reducing S to a relatively small fraction rapidly. Since μ is a rate, we mimic a step-wise hard lock-
155 down by setting a high value to μ , but its effect only lasts for a short period of time, see Fig. 4b. We
156 thus use the notation μ_{ld} . In the figure, an example shows how to rapidly protect about 68% of the
157 population with a step-wise μ_{ld} function. In particular, we use an average four-days long step-wise μ_{ld}
158 function (Fig. 4b) to mimic the rapid, but not abrupt, change in mobility observed in many countries by
159 Google Mobility Reports [21] (Fig. 4c). Lock-down effects are reported in Fig. 4a: a hard lock-down is
160 effective in suppressing the epidemic curve and in lowering the eradication time.

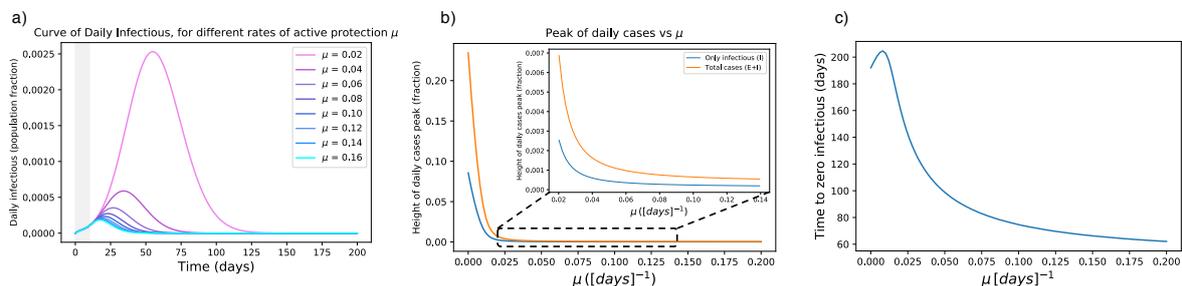

Fig. 3 (a) Effects of active protection on the infectious curve. The grey area indicates when measures are not yet in place. μ is expressed in d^{-1} . (b) Dependency of peak height on μ : the peak is rapidly flattened for increasing μ , then it is smoothly reduced for higher parameter values. (c) High μ values are effective in anticipating the complete eradication of the epidemic, but require protecting more than 90% of the population.

161 3.1.3 Only active quarantining

162 The simulations in this part are based on realistic assumptions: testing a person is effective only after
163 a few days that that person has been exposed (to have a viral charge that is detectable). This induces
164 a maximal quarantining rate θ , which we set $\theta = 0.33 d^{-1}$ as testing is often considered effective after
165 about 3 days from contagion [34]. Therefore, we get the active quarantining rate $\chi = \chi' \cdot \theta$, where χ' is a
166 tuning parameter associated e.g. to contact tracing. As θ is fixed, we focus our analysis on χ' . As above,
167 we also assume that testing starts after the epidemic is seen in the population, i.e. some infectious are
168 identified with the usual 10 days delay in the activation of measures.

169 The corresponding results are reported in Fig. 5. The curve is progressively flattened by latent carriers
170 quarantining and its peak suppressed, but the eradication time gets delayed for increasing χ' . This hap-
171 pens until a threshold value of $\chi'_{thr} = 0.9$ that pushes \hat{R} below 1. This value holds if we accept a strategy

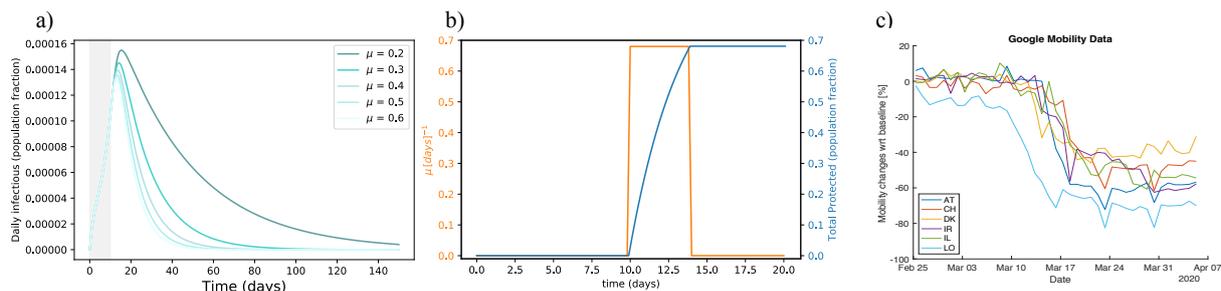

Fig. 4 (a) Flattening the infectious curve by hard lock-down. Rapidly isolating a large population fraction is effective in suppressing the epidemic spreading. (b) Modeling hard lock-down: high μ_{id} (orange) is active for four days to isolate and protect a large population fraction rapidly (blue). As an example, we show $\mu_{id} = 0.28 d^{-1}$ if $t \in [10, 14]$. It results in protecting about 68% of the population in two days. Higher values, e.g. $\mu_{id} = 0.65 d^{-1}$ would protect 93% of the population at once. (c) Google Mobility Report visualization [21] for analysed countries, around the date of measures setting. Each line reports the mean in mobility change across Retail & Recreation, Grocery & Pharmacy, Transit stations, and Workplaces, around the date of implementation of the measures. A minimum of 4 days (from top to bottom of steep decrease) is required for measures to be fully effective. Abbreviation explanations: AT = Austria, CH = Switzerland, DK = Denmark, IL = Israel, IR = Ireland, LO = Lombardy.

172 based on testing, with $\theta = 0.33$. If preventive quarantine of suspected cases does not need testing (for
 173 instance, it is achieved by contact tracing apps), the critical χ' value could be drastically lower. In partic-
 174 ular, $\chi'_{thr} = 0.3 d^{-1}$ if $\theta = 1 d^{-1}$, i.e. latent carriers are quarantined the day after a contact.
 175

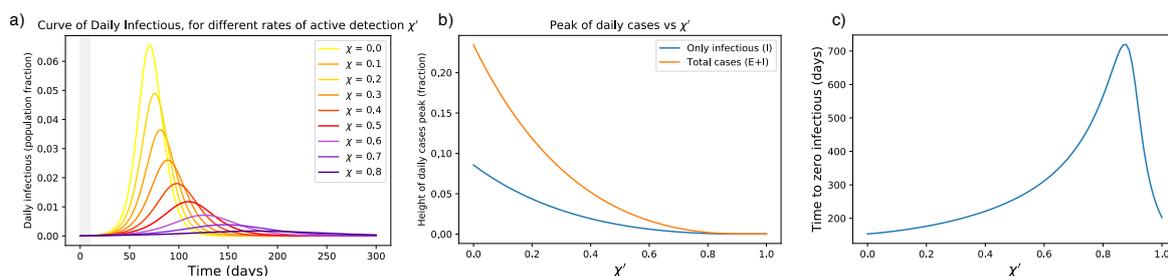

Fig. 5 (a) Effects of active latent carriers quarantining on the epidemic curve. The grey area indicates when measures are not yet in place. (b) The peak is progressively flattened until a disease-free equilibrium is reached for sufficiently large χ . (c) Unless χ' is large enough, stronger measures of this kind might delay the complete eradication of the epidemic. Note that the critical χ' can be lowered for higher θ , e.g. if preventive quarantine does not wait for a positive test.

The parameter χ' tunes the rate of removing latent carriers. Hence, it combines tracing and testing capacities, i.e. probability of finding latent carriers (P_{find}) and probability that their tests are positive (P_+). The latter depends on the false negative rate δ_- as

$$P_+ = (1 - \delta_-). \quad (4)$$

176 So, $\chi' = P_{find} \cdot P_+$. Hence, suppressing the peak of infectious requires an adequate balance of accu-
 177 rate tests and good tracing success as reported in Fig. 6. Further quantifying the latter would drastically
 178 improve our understanding of the current capabilities and of bottlenecks, towards a more comprehen-
 179 sive feasibility analysis.

180 3.2 Synergistic scenarios

181 Fully enhanced active quarantining and active protection might not be always feasible, e.g. because of
 182 limited resources, technological limitations or welfare restrictions. Therefore a synergistic approach is

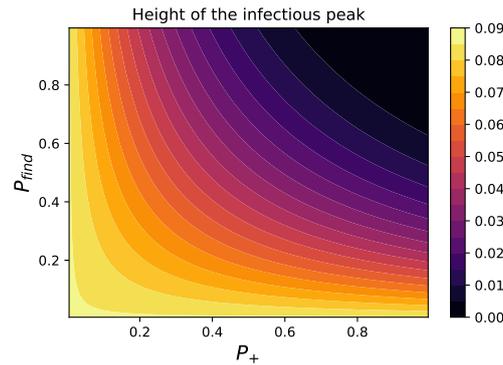

Fig. 6 Assessing the impact of P_{find} and P_+ on the peak of infectious separately. This way, we separate the contribution of those factors to look at resources needed from different fields, e.g. network engineering or wet lab biology. Solutions to boost the testing capacity like [35] could impact both terms.

183 very attractive as it can flatten the curve. This section shows a number of possible synergies, concentrat-
 184 ing as before on abstract scenarios to investigate the effect of combining different suppression programs.
 185 As case studies, we consider the 6 synergistic scenarios listed below. Parameters are set without being
 186 specific to real measures taken: their value is so far conceptual and meaningful when compared across
 187 scenarios. Just like above, we consider a 10 days delay from the first infection to issuing measures; as
 188 suggested in other studies [36], delaying action could worsen the situation. To differentiate between a
 189 rapid isolation and a constant protection, we introduce μ_{ld} (for “hard lock-down strategies”, see Sec-
 190 tion 3.1.2) separated from μ . To get \hat{R} , we follow Eq. 1, considering $\chi = \chi' \cdot \theta$ as in Section 3.1.3 and
 191 $T = 4$ (along the steep decay after measures are in place, in a best case scenario). Our scenarios are the
 192 following:

- 193 1. Many European countries opted for a lock-down strategy. A quite large fraction of the population
 194 was isolated, individuals were recommended to self-quarantine in case of suspected positiveness,
 195 social distancing got mandatory but was sometimes not fully followed, masks and sprays were
 196 suggested for protection. So, we set an initial “hard lock-down” $\mu_{ld} = 0.12 d^{-1}$ to protect around
 197 38% of the population quickly. Then we chose $\rho = 0.7$, $\chi' = 0.15$ and $\mu = 0.008 d^{-1}$. This yields
 198 $\hat{R} = 0.66$.
- 199 2. An alternative procedure is to rapidly protect only the population fraction at high risk ($\mu_{ld} =$
 200 $0.06 d^{-1}$, driving 15% of initial S to P). Then, we assume an improvement in individual safety
 201 giving $\mu = 0.01 d^{-1}$. Social distancing is relaxed ($\rho = 0.8$) but latent carrier quarantine is enforced
 202 ($\chi' = 0.5$). This gives $\hat{R} = 0.63$.
- 203 3. In case preventive quarantine of latent carriers is not greatly effective ($\chi' = 0.1$), and in case of low
 204 protection rate and scarce isolation ($\mu = 0.004 d^{-1}$, $\mu_{ld} = 0.08 d^{-1}$), we rise social distancing for all
 205 individuals doing business as usual ($\rho = 0.5$). In this case, $\hat{R} = 0.61$.
- 206 4. If there are no safety devices that provide an adequate protection ($\mu = 0 d^{-1}$), we set $\rho = 0.45$, $\mu_{ld} =$
 207 $0.2 d^{-1}$ and $\chi' = 0.2$ to get $\hat{R} = 0.51$.
- 208 5. This case has higher \hat{R} than the previous ones, namely $\hat{R} = 0.93$. The corresponding parameters
 209 are $\mu_{ld} = 0.1 d^{-1}$, $\mu = 0.002 d^{-1}$, $\rho = 0.7$, $\chi' = 0.1$.
- 210 6. Finally, we consider “draconian” measures such that $\hat{R} = 0.21$ only through isolation and massive
 211 latent carriers quarantining. So, $\mu_{ld} = 0.6 d^{-1}$ and $\chi' = 0.3$ while $\rho = 1$ and $\mu = 0 d^{-1}$.

212 Simulation results are reported in Fig. 7. Different synergies lead to different timing, even though the
 213 peak is contained similarly (Fig. 7a). This has an impact on the cumulative number of cases (Fig. 7b) that
 214 will be reflected on the death toll. This holds even when the \hat{R} values are very close, as in scenarios 1 to

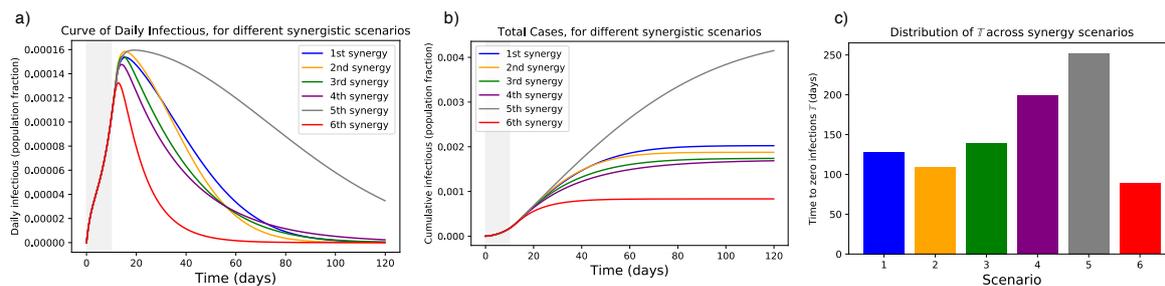

Fig. 7 Simulations of the 6 synergistic scenarios. (a) Curves of infectious Individuals, (b) Cumulative cases. The grey area indicates when measures are not yet in place. It is evident that scenarios leading to the same \hat{R} could show different patterns and suppression timing. (c) Distribution of times to zero infections \mathbb{T} for different scenarios.

215 4. Focusing on scenarios 2 and 3, we notice that prevention measures and latent quarantine accelerate
 216 the suppression, even when isolating only vulnerable people. This achieves similar effects as strong
 217 social distancing. In addition, active protective measures with relatively low values further concur in
 218 suppressing the peak. This finding asks for rapid assessment of masks and sanitising routines.
 219 Overall, the strength of suppression measures influences how and how fast the epidemic is flattened.
 220 μ_{id} mostly governs the peak height after measures are implemented, ρ mainly tunes the curve steepness
 221 together with μ , while χ shifts the decaying slope up and down. Overall, a $\hat{R} < 1$ suffices to avoid
 222 breakdown of the health system, but its effects could be too slow for the economic system. Decreasing
 223 its value with synergistic interventions could speed up epidemic suppression. A careful assessment of
 224 measures' strength is thus recommended for cross-country comparison.

225 3.3 Model fitting and interventions assessment

226 3.3.1 Model fitting

227 As described in the Methods section, we first estimate the "model consistent" date of first infection t_0 ,
 228 that is, the temporal initial condition for the SPQEIR model. We do not claim that this is the true date of
 229 first infection in a country. On the contrary, it is the starting date of infections in case of homogeneous
 230 transmission, under the assumption of no superspreading events [37], and with the hypothesis of co-
 231 herent R_0 (cf. Table 2). During the second fitting step, we also estimate the date at which suppression
 232 measures start having effect on the infectious curve, t_m . Comparing t_m with official intervention dates
 233 from Table 1, we notice that about 8 days are necessary to register lock-down effects. This is consistent
 234 to early findings on lock-down effectiveness [38]. Estimated dates are reported in Table 3.

Country	AT	DK	IR	IL	LO	CH
1 st official detection	24 Feb	04 Mar	29 Feb	21 Feb	21 Feb	25 Feb
t_0	22 Jan	22 Jan	29 Jan	24 Jan	05 Jan	14 Jan
t_m	26 Mar	21 Mar	06 Apr	30 Mar	19 Mar	21 Mar

Table 3: Dates of official detection of first COVID-19 case [18], estimated dates for first infection t_0 (ac-
 cording to Eq. 2) and date at which measures start being effective t_m , per country. Although consistent
 with recent literature [26] that suggests the first infection happened weeks before the first official detec-
 tion, these retrospective dates should be interpreted under the model assumptions.

235 Then, we fit suppression parameters to data affected by policy measures, from their estimated start-
 236 ing date t_m to phase-out t_p (cf. Table 1). Results of the model fitting are reported in Fig. 8. The SPQEIR
 237 model, with appropriate parameters for each country, is fitted to reported infection curves and, overall,
 238 model fitting have good agreement with data. This supports the model structure as very simple yet
 239 realistic enough to capture the main dynamical behaviour of the infection curves in multiple countries.
 240 In addition, it allows for each country to obtain multiple sets of parameters, providing a good fit and
 241 representing different strategies. Finally, it allows a comparison between different countries through the

242 corresponding best fit parameters. For Ireland, although initial social distancing advises were issued on
243 13th March (cf. Table 1), fitting the complete curve was only possible when considering the lock-down
244 date (28th March) as the major driver of the suppression.

245 The model matches very well those regions like Austria and Switzerland that avoided saturation of the
246 healthcare system and thus reported reliable data (cf. Fig. 4c). Ireland reported intermittent data, while
247 Lombardy is not perfectly represented, probably because of data reporting and larger heterogeneity in
248 its spacial patterns.

249
250 Finally, the reduced χ^2 metric (Eq. 3) usually attains minimum values for the complete SPQEIR
251 model rather than the simple social distancing one. Hence, the SPQEIR is confirmed to be informa-
252 tive, on top of being fully interpretable and linked to recognised social policy categories.

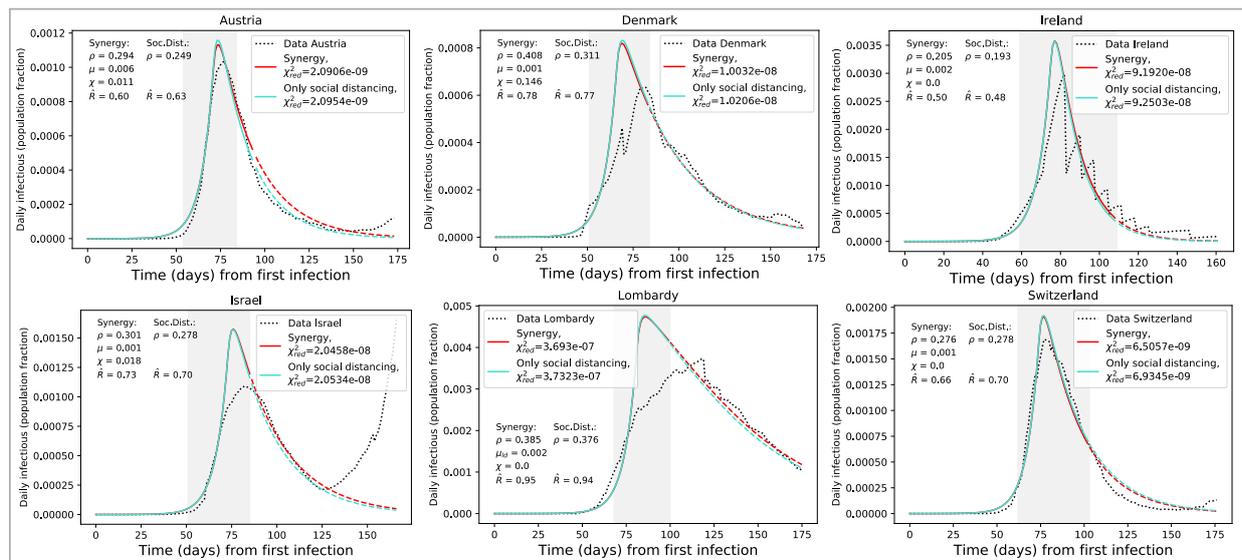

Fig. 8 Results of model fitting. Infection curves for the considered countries (dotted) are fitted with the SPQEIR model with appropriate parameters (red curves). We also show a comparison with the fitted curve obtained from the “basic” SEIR model with only social distancing (turquoise curves). Parameter values are reported for each country, as well as the corresponding \hat{R} (for the gray area, following Eq. 1) and χ_{red}^2 . The period of measures enforcement, from t_m to t_p , is highlighted by the grey region. Time progresses from the estimated day of first infection t_0 (cf. Table 3). Population fraction refers to country-specific populations (cf. Table 1). After phase-out, we prolong the fitted curve (parameter values unchanged) to compare observed data with what could have been if measures had not been lifted (dashed lines). From the data, we can observe a resurgence of cases that points to possible “second outbreaks” (particularly in Israel).

253 3.3.2 Cross-country interventions assessment

254 Fitting a number of countries with the same model containing the same epidemiological parameters
255 allows to perform a quantitative and consistent comparison on the efficacy of their interventions. In Fig.
256 8, parameter values providing the best fit of model to data are reported, together with the simulation
257 results (mean values) calculated by *lmfit* algorithm. Different synergies yield similar values for \hat{R} , but
258 the curve is different in its evolution as already observed in the previous sections. As expected from
259 the model analysis above, the lower \hat{R} is (below 1), the faster the suppression of the epidemic. In addition,
260 different parameter combinations generate differing curves, which might well explain differences
261 in reported total cases and deaths between various countries. Comparing Austria, Denmark and Lom-
262 bardy we can see that contact tracing and monitoring might play a role in speeding up the curve decay,
263 despite the fact that population-wide interventions played a major role. In general, combined isolation
264 and tracing strategies would reduce transmission in addition to social distancing or self-isolation alone.
265 In particular, social distancing alone is effective only if very stringent, as suggested by “only social dis-

266 tancing" fitting. In general, a strong, rapid lock-down seems the best option, as also suggested by the
267 conceptual analysis. However, intervening with additional synergies is a viable option to suppress the
268 epidemic faster and with lower lock-down values.
269 Finally, we observe the value of timely interventions: we see that intervening earlier with respect to
270 the date of first infection helps reducing the daily curves by almost a factor of 10. For instance, we can
271 compare Denmark and Lombardy in Fig. 8: the first one got a peak corresponding to about 0.08% of
272 the whole population, while the second region registered a number of active cases of about 0.5% of the
273 whole population. This translates in more than 3800 infectious on the Danish peak, and on more than
274 37000 on Lombardy's.

275 4 Discussion

276 The model is fitted until phase-out dates, when measures are progressively lifted and therefore the
277 model assumptions do not hold anymore. In Fig. 8 we extrapolate the model, with same parameter
278 values, after phase-out (dashed lines), to compare observed data to the most optimistic scenario, where
279 measures would not have been lifted. We observe that, up to July 8th, the infection curves mostly main-
280 tained an inertial decreasing trend: despite some fluctuations that make them generally higher than the
281 best scenario, they kept on following a downward trend similar to that of the model. We speculate that
282 this phenomenon is linked to changed behaviors, face masks [39] and improved sanitising practices that
283 maintained social distancing values, as well as contact tracing practices issued by many countries along
284 with the phase-out. However, some countries (Israel in particular, but also Austria) showed a worri-
285 some upward trend, possibly associate to a second outbreak. As this is not a low probability event, we
286 stress the usefulness of our analysis to prepare for future developments in pandemic progression.
287 It has been asked whether the peak of infections was reached because of herd immunity or because of
288 interventions [40]. An added value of this study is to confirm that the peak of infection, for the consid-
289 ered countries, was not reached because of herd immunity. On the contrary, it is the effect of a number
290 of suppression measures that reduced the number of cases artificially. This should warn about the high
291 numbers of people that are still susceptible.

292
293 We acknowledge the limitations of our analysis. Due to its structure and the use of ordinary differ-
294 ential equations, the model only accounts for average trends. However, it cannot reproduce fluctuations
295 in the data, being them intrinsic in the epidemic, or from testing and reporting protocols that might
296 differ among countries. In addition, the constant nature of parameters used in this analysis allows good
297 agreement between model and data when countries implemented rapid and strong measures point-wise
298 in time, with little follow-ups. Further statistical studies, with time varying parameters, could obtain
299 more precise values. In the same way, transferring models from country to country requires fulfilling
300 the same assumptions on model structure and basic hypothesis. This is shown by the different fitting
301 performances, that suggest that a transfer is not always possible.

302 In general, this study is not intended to make a ranking of country responses, nor to suggest that differ-
303 ent strategies could have led to better outcomes. Contrariwise, it should be used as a methodological
304 step towards quantitatively inquiring the effect of different intervention categories. It examines possible
305 abstract scenarios and compares quantitative, model-based outputs, but it is not intended to fully repre-
306 sent specific countries nor to reproduce the epidemic complexity within societies. In fact, the model does
307 not provide fine-grained quantification of specific interventions, e.g. how effective masks are in protect-
308 ing people, how much proximity tracing apps increase P_{find} , how changes in behavior are associated
309 with epidemic decline [41] and so on. We acknowledge that the new compartments cannot perfectly
310 match policy measures, but are a reasonable approximation. Some real measures might also affect mul-
311 tiple parameters at once, e.g. safety devices and lock-down could impact both μ and ρ . Comparing
312 results of this macro-scale model with those of complex, micro-scale ones [3] could inform researchers
313 and policy makers about the epidemic dynamics and effective synergies to hamper it. Any conclusion
314 should be carefully interpreted by experts, and the feasibility of tested scenarios should be discussed
315 before reaching consensus.

316 5 Conclusion

317 We have developed a minimal model to link intervention categories against epidemic spread to epidemi-
318 ological model compartments. This allows quantitative assessment of non-pharmaceutical suppression
319 strategies on top of social distancing, for a number of countries. Strategies have different effects on epi-
320 demic evolution in terms of curve flattening and eradication timing. As with previous studies [22, 42],
321 we have observed the need to enforce containment measures (i.e., detect and isolate cases, identify and
322 quarantine contacts and at risk neighborhoods) along with mitigation (i.e., slow down viral spread in
323 the community with social distancing).

324 By extending the classic SEIR model into the SPQEIR model, we distinguished the impact of differ-
325 ent suppression programs in flattening the peak and anticipating the eradication of the epidemic. De-
326 pending on their strength and synergy, non-pharmaceutical interventions can hamper the disease from
327 spreading in a population. First, we performed a complete sensitivity analysis of their effects, both
328 alone and in synergy scenarios. Then, we moved from idealised representations to fitting realistic con-
329 texts, allowing preliminary mapping of intervention categories to abstract programs. We verified that
330 the model is informative in interpolating the infection curves for a number of countries, and performed
331 cross-country comparison. We could then obtain model-based outputs on the strength of interventions,
332 for a number of countries that respected the model assumptions. This provides better, quantitative in-
333 sights on the effect of suppression measures and their timing, and allows improved comparison.

334
335 Overall, this work could contribute to quantitative assessments of epidemic suppression strategies.
336 To tackle current epidemic waves, and against possible resurgence of contagion [43] (also cf. Fig 8),
337 better understanding the effect of different non-pharmaceutical interventions could help planning mid-
338 and long-term measures and to prepare preventive plans, until a vaccine is available.

340 6 Shinyapp

341 A user-friendly online shinyapp to interactively simulate different scenarios with the SPQEIR model
342 is available on: https://jose-ameijeiras.shinyapps.io/SPQEIR_model/. It allows to repro-
343 duce the present outputs and to perform sensitivity analysis.

344 Ethics

345 The application of anonymized data for the purpose of epidemic modelling has been endorsed by the
346 accessed databases.

347 Data accessibility

348 Databases of social measures can be accessed at [https://www.who.int/emergencies/diseases/

358 **Authors' Contributions**

359 DP, AH designed the study. DP, FK, SM developed the model. DP, FK, JAA implemented the model. DP,
360 FK, SM, AH, AA, LM, AS, JG, CL analyzed and interpreted the results. SM, AH, AS, JG, CL supervised
361 and coordinated the project. DP, FK, SM, CL wrote the first draft. All authors contributed to the final
362 draft. All authors gave their final approval for publication.

363 **Competing interest**

364 The authors declare no competing interests.

365 **Funding**

366 Fundings: DP and SM's work is supported by the FNR PRIDE DTU CriTiCS, ref 10907093. FK's work is
367 supported by the Luxembourg National Research Fund PRIDE17/12244779/PARK-QC. A.H. work was
368 partially supported by the Fondation Cancer Luxembourg. JG is partly supported by the 111 Project on
369 Computational Intelligence and Intelligent Control, ref B18024. AA is supported by the Luxembourg
370 National Research Fund (FNR) (Project code: 13684479). JAA is supported by the FWO research project
371 G.0826.15N (Flemish Science Foundation), GOA/12/014 project (Research Fund KU Leuven), Project
372 MTM2016-76969-P from the Spanish State Research Agency (AEI) co-funded by the European Regional
373 Development Fund (ERDF) and the Competitive Reference Groups 2017–2020 (ED431C 2017/38) from
374 the Xunta de Galicia through the ERDF. LM and AA are partly supported by FNR COVID-19 Fast-Track
375 (project PREVID 14863306).
