Abstract

Aim: Despite its high frequency of occurrence, mild traumatic brain injury (mTBI), or concussion, is difficult to recognize and diagnose, particularly in pediatric populations. Conventional methods to diagnose mTBI primarily rely on clinical questionnaires and sometimes include imaging such as computed tomography (CT) or pencil and paper neuropsychological testing. However, these methods are time consuming, require administration/interpretation from health professionals, and lack adequate test sensitivity and specificity. We explore the use of BrainCheck, a computerized neurocognitive test that is available on iPad, iPhone or computer desktop, for mTBI assessment. The BrainCheck battery consists of 6 gamified traditional neurocognitive tests that assess areas of cognition vulnerable to mTBI such as attention, processing speed, executing functioning, and coordination.

Methods: We administered BrainCheck to 10 participants diagnosed with mTBI at the emergency department (ED) of Children's hospital within 96 hours of admittance to the ED, and 126 normal controls at a local high school. Statistical analysis included Chi-Square tests, Analysis of Variance (ANOVA), independent sample t-tests, and Hochberg tests to examine differences between mTBI, diagnoses by current gold standard clinical exam, and control groups on each assessment in the battery. Significant metrics from these assessments were used to build a logistic regression model that distinguishes mTBI from non-mTBI participants.

Results: BrainCheck was able to detect significant differences in coordination, Flanker, Stroop, Digital Symbol, Immediate/Delayed recall and recognition assessments between normal people and mTBI patients. Receiver operator score (ROC) analysis of our logistic regression model found a sensitivity of 84% and specificity of 80%.

Conclusions: BrainCheck has potential in distinguishing mTBI from non-mTBI participants, by providing a shorter, gamified test battery to assess cognitive function after brain injury, while also providing a method for tracking recovery with the opportunity to do so remotely from a patient's home.

Keywords:
mTBI, Concussion, BrainCheck, Neurocognitive testing

Introduction

Mild traumatic brain injury (mTBI) is an increasing public health concern not only due to its growing frequency of occurrence but lack of guidelines and biomarkers that make diagnosis challenging [1]. Recent evidence also indicates an association to the development of neurodegenerative diseases [2]. This is particularly concerning in the pediatric population whose ongoing cognitive maturation makes them more vulnerable to head injury than the adult population [3]. The diagnostic utility of neuroimaging is limited and current recommendations do not recommend routine imaging for mTBI unless otherwise clinically indicated [1]. Furthermore, literature evaluating sports-related concussions (SRCS) has indicated that young athletes with mTBI may not recognize alarming symptoms due to a lack of awareness, understanding, or as a result of their cognitive impairment [4]. Thus, self-reported post-concussion symptoms are not reliable in this population. Additionally, while there are several concussion grading systems, there is little agreement between the systems on how they define and assess mTBI, and a collectively agreed gold-standard grading system does not exist [5]. Self-reporting concussion symptoms is often at odds with social pressures on a younger person to perform both educationally and athletically and places a strong bias making these measures more inaccurate [6].

Although neuropsychological tests were developed to more accurately measure cognitive deficits in mTBI, these tests have their limitations. Typically they require a neuropsychologist or psychometrist to administer, score, and interpret the results of the battery of tests. More importantly, they lack adequate test sensitivity and specificity, and are susceptible to practice effects which occur when tests are repeated more than once [7].

BrainCheck is an alternative solution to mTBI assessment that is rapid and self-administered. BrainCheck Sport battery is a computerized neurocognitive test that assesses various areas of cognition, such as attention, processing speed, coordination, and executive functioning. Its diagnostic accuracy was previously validated as a testing method for traumatic brain injuries and it is classified as a diagnostic aid by the FDA [8] . We also evaluated the differences between 10 pediatric participants with mTBI diagnosed by physicians at the Emergency Department and 126 control subjects at a local high school on their Braincheck battery assessments and utilized the

subsequent metrics to build a logistic regression model that distinguishes mTBI from non-mTBI participants. Receiver operator score (ROC) analysis of our logistic regression model found a sensitivity of 84% and specificity of 81%, which confirmed Braincheck's potential in assessing cognitive function after brain injury, while also providing a method for tracking recovery remotely from a patient's home. Thus, the primary objective of this study is to assess the utility of BrainCheck as a diagnostic tool in evaluating mTBI in the pediatric population.

Materials and methods

This study was approved by the Baylor College of Medicine institutional review board. It took place at the emergency department (ED) of Texas Children's Hospital (TCH) in Houston, TX and Morton Ranch High School in Katy, TX. We recruited 136 participants in this study, which includes 126 participants in the control group and 10 participants in the mTBI group. Subjects were included in the study if they received an official physician's diagnosis of mTBI. The recruited volunteers were either enrolled in athletic programs at Morton Ranch or patients at the TCH ED. For the control group we used baseline tests from healthy Morton Ranch athletes, aged 13 to 18 years. One outlier had an extremely high score in the Digit Symbol Substitution Task was removed. After excluding participants who had a history of mTBI or malingered, we were left with 122 participants in the control group and 9 participants in the mTBI group.

Test Administration

mTBI participants were administered Version 3 of the BrainCheck Sport battery on the iPad within 96 hours of injury by an ED nurse if recruited at TCH or by an athletic trainer if recruited by Morton Ranch. Control participants, composed of Morton Ranch athletes, were administered the BrainCheck test by a research coordinator prior to the athletic season. Prior to the actual BrainCheck test battery, mTBI participants took the Post mTBI Symptom Scale derived from the SCAT3.

Test Measures

A short description of each assessment that comprises the BrainCheck battery are listed in Table 1. A more detailed description provided of the battery has been described previously [8].

Table 1. Neuropsychological assessments in BrainCheck battery

Assessment	Description	Measurement
Flanker	We presented participants with a target arrow pointing to the left or right. The target was surrounded by congruent ($>>>>$), or incongruent ($<<><<$) arrows. Participants identified the direction of the target as quickly and accurately as possible.	Reaction time
Digit Symbol Substitution	Participants must match an arbitrary correspondence of symbols to digits; when presented with a new symbol, they input as quickly as possible the corresponding digit.	Cognitive processing
Stroop	Participants are instructed to find a word matching the given name of a color. There are two types of trials: CONGRUENT in which the word name and font color are the same (e.g., the word RED presented in red font), and INCONGRUENT in which the word name indicates a different color than the font (e.g., the word RED presented in green font).	Cognitive executive function
Trail Making	Participants are instructed to connect a set of 25 dots in their correct order as rapidly as possible. Trail Making Test A uses only numbers (1 through 25), while Trail Making Test B employs alternating letters and numbers (1 – A – 2 – B – 3 – C - …).	Visual attention and cognitive flexibility
Coordination	A ball is displayed on the tablet, moving according to the tilt of the tablet. A participant holds the tablet out in front at arm's length, and tilts it appropriately to keep the ball in a central circle.	Coordination ability
Immediate and Delayed Recognition	First, immediate recall is measured by serially displaying 10 words, and then asking whether a word was just seen—either a distractor word or a target word (20 trials). At the end of the testing battery, without seeing the original list again, participants are again presented with 20 words and asked whether each word was presented before.	Memory

Statistical Analyses

Chi-square tests and Analysis of Variance (ANOVA) were used to examine differences in age and gender in the mTBI and control groups. Independent sample t-tests were used to compare groups on each assessment metric and the Hochberg test was used to adjust p values for multiple comparisons. For each kind of assessment, only the most significant metric was used in our

logistic regression model. Sensitivity and specificity of the overall battery was evaluated using receiver operating characteristic (ROC) curve analyses with a cutoff score that represented the maximum values sensitivity and specificity could reach. Data analysis was performed using the R statistical programming language in RStudio version 3.3.1.

Results

Demographics

The overall gender distribution was unbalanced because most athletes participated in the study were males (Figure 1). Enrolled participants aged from 8 to 26 years (Figure 2). Nevertheless, there was no statistically significant difference in gender between patients and controls (X-squared (1) = 0.005, p = -0.94). Similarly, no significant difference in age was detected between patients and controls (F(1, 130) = 0.016, p = 0.9).

Figure 1. Gender distribution of participants

Figure 2. Age distribution of participants

Assessments scores on mTBI

The Braincheck assessments evaluate different cognitive domains of patients. As shown in Figure 3 and Table 2 below, we found that mTBI and control participants showed significantly difference on raw scores of delayed recall ($t_{61.5}$ = 4.409, p<0.01), immediate recall ($t_{52.4}$ = 4.8192, p<0.01), the Stroop test ($t_{61.6}$ = -4.693, p<0.01), and the Coordination test ($t_{79.8}$ = 3.7075, p<0.01). In contrast, no difference was detected on the Trail Making test ($t_{72.4}$ =-0.64, p=0.52 for trails A,

$t_{66.7} = -0.83$, p = 0.4 for trails B), the Flanker test ($t_{62.8} = 2.0934$, p = 0.056) and the Digit Symbol Substitution test ($t_{45} = -2.0879$, p = 0.056).

Table 2. Benjamini-Hochberg adjusted P value for assessment comparison between mTBI group and control group. Statistically significant metrics are listed in bold.

Assessment	Metrics	Adjusted p value	Explanation
Coordination	**balance_mean_distance_from_center**	**0.02**	**Mean radial distance from center circle**
	balance_percent_in_target_mean	**0.001**	**Mean of percentage time in circle**
	balance_position	**0.02**	**Mean position from the circle center**
	balance_total_duration_in_circle	**0.0015**	**Total duration time in circle**
	balance_total_duration_out_circle	**0.0015**	**Total duration time out of circle**
	balance_total_duration_unpressed	0.76	Total duration time not pressing the screen
	balance_total_number_exits	0.92	Total number of times existing the circle
Digit Symbol Substitution	digit_symbol_correct_per_second_mean	0.58	Mean of correct responses in a second
	digit_symbol_duration	0.094	Total time taken to complete assessment. Time starts after digit display and ends when correct answer is completed
	flanker_correct_mean	0.094	Mean of correct responses

Flanker	flanker_reaction_time_central_mean	0.58	Mean reaction time of all correct responses in central cue trials
	flanker_reaction_time_congruent_mean	0.92	Mean of all reaction times when arrows point in same direction
	flanker_reaction_time_correct_mean	0.48	Mean reaction time of all correct responses
	flanker_reaction_time_correct_median	0.38	Median reaction time of all correct responses
	flanker_reaction_time_incongruent_mean	0.58	Mean of all reaction times when arrows point in opposite directions
	flanker_reaction_time_incorrect_mean	0.48	Mean reaction time of all incorrect responses
	flanker_reaction_time_spatial_mean	0.83	Mean reaction time of all correct responses in spatial cue trials
Immediate and Delayed Recognition	**delayed_recall_correct**	**0.0004**	**Number of correct responses**
	immediate_recall_correct	**0.0002**	**Number of correct responses**
Stroop	stroop_basic_reaction_time_mean	0.79	Mean reaction time for neutral words
	stroop_basic_reaction_time_median	0.92	Median reaction time for neutral words
	stroop_effect_ms_mean	**0.001**	**Mean reaction time incongruent - congruent (in ms)**
	stroop_effect_ratio	**0.0002**	**Median reaction time of incongruent / median reaction time of congruent**

	stroop_reaction_time_congruent_mean	**0.015**	**Mean reaction time for all correct answers in congruent trials**
	stroop_reaction_time_incongruent_median	**0.048**	**Mean reaction time for all correct answers in incongruent trials**
Trail Making	trails_b_duration_median	0.58	Median of response times between each click for Trail Making B
	trails_b_duration_mean	0.55	Mean of all response times between clicks for Trail Making B
	trails_a_duration_mean	0.69	Mean of all response times between clicks for Trail Making A

Figure 3. Boxplots of Braincheck assessments metrics for the control group and the mTBI group.

Our results demonstrate that objects that suffered from mTBI exhibited worse performance in Braincheck's assessments of memory, executive and coordination on the battery, which are consistent with studies conducted golden standard neuropsychological tests [9]–[11]. In addition, they showed no significant deterioration in their cognitive performance and attention, which has also been observed in previous studies [12,13] .

Logistic regression

In our logistic regression model, 30 observations were deleted due to missing data, therefore it utilized 92 of the participants in our control group and 9 of the participants in our mTBI group. We used "delayed_recall_correct", "stroop_effect_ratio", "immediate_recall_correct", "balance_percent_in_target_mean", "digit_symbol_duration", "flanker_correct_mean", "trails_a_duration_mean", "trails_b_duration_median" as factors in our model. Based on the

logistic model, the Stroop test, the Immediate Recall test, the Coordination and Trail-making were statistically significant at   , while the rest were not statistically significant. Here, we used receiver operating characteristic (ROC) analysis methods to determine the optimal threshold for the logistic regression model so that the model could achieve the maximum sensitivity and specificity to distinguish between control and mTBI group. We found that the BrainCheck Sport battery could achieve a sensitivity of approximately 84% and a specificity of 81% when we chose 0.3 as the optimal decision threshold (Refer to ROC curve in Figure 4). In other words, if the model predicted probability for a subject is greater than 0.3, the subject is categorized to the mTBI group.

Figure 4. ROC curve of logistic regression.

Discussion

The findings of this study demonstrated that BrainCheck Sport is able to discriminate mTBI patients from the control group on some battery assessments, and achieves decent levels of

sensitivity (84%) and specificity (81%) when classifying mTBI. This is achieved by evaluating the cognitive function, memory, and coordination of the participants under tests. The results reflect that Braincheck Sport would be as effective of a diagnostic aid in the pediatric population as it would be in the adult population [8].

Our results demonstrate that after mTBI, patients experience deficits on immediate and delayed recall tests; balance and coordination tests; and the Stroop color tests which represent deficits in cognitive domains consisting of short term memory; coordination; and executive function, specifically inhibition and attention, respectively. These are typical symptoms observed after concussions. We did not observe degradation in patient performance on trail making; digit-symbol substitution; or the Flanker tests which represent cognitive domains consisting of executive function, specifically, cognitive flexibility; information processing and speed; and visual attention, respectively. As suggested by previous studies, not all cognitive domains of concussion patients will be affected [12,13] . However, De Beaumont et al. [14] found that athletes with concussion history performed worse in the Flanker Test. This might be due to the repeated injuries these athletes sustained and became significant over time. In our study we excluded participants with mTBI history, and participants were relatively young. Therefore, it is likely their symptoms differ from those who have experienced repeated concussions over time and are older. On the other hand, the majority of our participants are only assessed within 48 hours after injury leaving time for symptoms to possibly resolve. Further studies should control for time of administration after injury more stringently by restricting the timeframe to within 24 hours or less.

It is important to keep in mind that our participants were from an atypical population. The control group used was composed of athletes and was not fully representative of the pediatric population. Since the mTBI experimental group included both sports related and non-sports related mTBIs, a control group with similar demographics would have contributed to a more balanced design. We also sacrificed statistical power with a smaller mTBI group, which may have resulted in less separation of groups in our significance tests. A larger experimental group with more individuals in the mTBI group would likely give more robust results. It is possible to have a large range of symptoms after concussion with a range of cognitive impairment which is

likely present in our data. Having a larger dataset would minimize the effects of this variation within the concussion population. In addition, both our experimental and control groups were composed of only a few females. Such gender differences in mTBI injury severity have been reported in previous literature [15]. To investigate whether there are gender differences in the neurocognitive measures examined in the BrainCheck battery, future research should utilize a more evenly distributed ratio of males to females in the participants pool. Additionally, despite being a statistically significant predictor, the coordination test occasionally suffered from software malfunctioning during testing, and resulted in several cases of missing data in both the experimental and control groups. As a retrospective study, it is hard to determine if all cases of malfunctioning were properly documented and fully taken into consideration.

Currently there are a variety of different test batteries and screeners used in clinical practice to aid in the diagnosis of mTBI. BrainCheck provides another option among the computerized neurocognitive tests by providing a shorter, gamified test battery that attempts to comprehensively examine and assess cognitive functioning after brain injury. Here we demonstrate BrainCheck performs well in detecting and classifying mTBI patients, which may be useful as a diagnostic aid.
