Risk stratification

Health care worker

Summary

Healthcare workers have a greater exposure to individuals with confirmed SARS-novel coronavirus 2, and thus a higher probability of contracting coronavirus disease (CoViD)-19, than the general population. Employers have a duty of care to minimise the risk for their employees. Several bodies including the Faculty of Occupational Medicine, NHS Employers, and Public Health England have published a requirement to perform risk assessments for all health care workers, however, with the absence of an objective risk stratification tool, comparing assessments between individuals is difficult if not impossible. Using published data, we explored the predictive role of basic demographics such as age, sex, ethnicity and comorbidities in order to establish an objective risk stratification tool that could help risk allocate duties to health care workers. We developed an objective risk stratification tool using a Caucasian female <50years of age with no comorbidities as a reference. Each point allocated to risk factors was associated with an approximate doubling in risk. This tool was then validated against the primary care-based analysis. This tool provides objective support for employers when determining which healthcare workers should be allocated to high-risk vs. lower risk patient facing clinical duties or to remote supportive roles.

Strengths and limitations of this study

- There is an increased risk of mortality in the clinical workforce due to the effects of CoViD-19.
- This manuscript outlines a simple risk stratification tool that helps to quantify an individual's biological risk
- This will assist team leaders when allocating roles within clinical departments.
- This tool does not incorporate other external factors, such as high-risk household members or those at higher risk of mental health issues, that may require additional consideration when allocating clinical duties in an appropriate clinical domain.
- This population-based analysis did not explain for the very high risk observed in BAME healthcare workers suggesting there are other issues at play that require addressing.

The Health and Safety executive mandate that all employers protect their employees from harm under the Management of Health and Safety at Work Regulations 1999. There are three key elements to this, identify what could cause the injury, decide how likely that someone could be harmed and how seriously they are likely to be harmed, and what actions can be taken to minimise this risk. In the current coronavirus pandemic, it is clear the corona virus disease (CoViD-19) is the agent that causes injury. The risk of harm is higher in healthcare workers compared to the general population¹, and thus action is required to minimise this risk.

The increased risk among health care workers has been challenged in reports that amalgamate all workers in the health service, irrespective of whether they have a patient facing role or not.² When incorporating roles such as podiatrists and psychologist who have had minimal patient contact during the outbreak with acute care staff, there is no increase rate of mortality due to CoViD-19 compared to the general population. However, within this analysis of one month's data, medical practitioners had a 2.5-fold increase (95% CI 1.5-4.3) in mortality compared to the average mortality from 2014-2018. This compared to a 50% increased risk in the age-matched general population (HR 1.5, 95%CI 1.5-1.6). This trend was in keeping with observations in other countries of higher mortality amongst health care workers³⁻⁷.

At the outset of the pandemic, NHS Digital produced a Shielded Patient List (SPL) identified high risk individuals, such as those aged >70years, on chemotherapy, and pregnancy advising them to "shield" from the virus by behavioural modification.⁸ These parameters are based on conditions previously identified as requiring an annual flu vaccination. The demographics of those adversely affected by CoViD-19, however, is substantially different from the majority of seasonal flu and previous coronaviruses. As a result, existing stratification methods are unlikely to encompass the peculiarities of this disease.

Whilst reasonable measures must be taken to protect all staff members from infection, individuals thought to be at particularly high-risk from infection may require modification of their practice. In response to the increased risk in healthcare workers populations not previously recognised, the Faculty of Occupational Medicine and NHS Employers in England

produced recommendations that all health care practitioners should receive an occupational risk assessment^{9 10}. These frameworks were borne of the observation that certain ethnic groups appeared to be at higher risk than others¹⁰. Whilst ethnicity remains a significant predictor of adverse outcomes, there are several other biological parameters, such as age, male sex, prior cardiovascular disease, and diabetes that were also associated with adverse outcomes. These predictors of hospitalisation, progression to intensive care units, and ultimately death were been reaffirmed in the Public Health England document¹¹.

Despite the intention to improve risk assessment in healthcare settings, these frameworks failed to produce an objective tool in order to improve stratification across the health care system. The need for an such a tool is highlighted by the disproportionate impact of CoViD-19 on healthcare workers of black, Asian and minority ethnicity (BAME) descent. Up to the 21st April 2020, 36% and 27% of the fatalities came from people of Indian Asian heritage and Black African descent respectively, despite those populations only representing 10% and 6% of the work force. Existing data suggest biological parameters do not account for all this increased risk, raising the possibility of cultural differences in self-assessment of risk or systemic challenges in modification of hazards for people of different ethnic background. Indeed, these cultural challenges have been proposed as a contributor to the increased risk in BAME populations.

Using published data on the demographics of those who have been hospitalised, and ultimately died, due to CoViD-19 compared to the general population prevalence in these determinants we have developed an objective risk stratification tool. Creation of such an objective tool that can be applied equally and without favour to all health care practitioners allows biological risk to be evaluated and used to reduce hazard.

Methods.

We reviewed the published literature (including multiple search strategies in MEDLINE with PubMed interface) and critically assessed early reports on medRxiv, a pre-print server (<https://www.medrxiv.org/>) (date of last search: June 4, 2020). Given there are selection biases in testing for coronavirus, CoViD-19 care and reporting, we explored predominantly the 'hard outcomes' of mortality and admission to the intensive care unit. Further, the

majority of the existing analyses are based on retrospective and often single-centre series. No published or completed prospective cohort studies or randomized controlled trials were present in this literature search. We reviewed the case reports and cohort studies and where possible the local demographics. Risk for age¹², ethnicity¹³, socioeconomic status¹³, and co-morbidities¹⁴ was normalised to a female aged 40-49.

There were two principle sources of data; the intensive care national audit and research centre (ICNARC) report which collated data from the national clinical audit covering all NHS adult, general intensive care and combined intensive care/high dependency units in England, Wales and Northern Ireland, plus some additional specialist and non-NHS critical care units, and the OPENSAFELY report which quantified a range of risk factors for death from CoViD-19 based on primary care records. Given these two principle sources of data, we collated and compared to the risk of admission to ITU and mortality from the ICNARC study with general population data. Predictive risk modelling was used to predict adverse future events for individuals. This risk tool was standardised to the risk of mortality of a female under the age of 50 years. A point was then allocated for each approximate doubling in risk. Given the likely co-linearity of multiple risk factors where risk was a greater multiple than two it was rounded down. Since the purpose of this objective risk assessment tool is to supplement rather than supplant existing Public Health England recommendations, characteristics that warranted shielding according to the NHS Digital SPL algorithm were discounted.

Once a simplified risk tool was compiled this was validated using the composite hazard ratios derived from the OpenSafely platform report.¹⁵ We evaluated the risk in 98 cases within a trust and stratified them into low, middle and high risk. Agreement between the objective risk assessment tool and the calculated hazard ratio was evaluated using Cohen's kappa coefficient for inter-rater agreement.

Results

Multiple global observational studies were identified describing the risk of hospitalisation and mortality due to CoViD-19, however there was significant heterogeneity in these studies, such that the robust nature of the data when applying to a UK population of health

care providers was questionable (Supplementary table 1). One point of agreement, however, was that multiple co-morbidities appeared to confer cumulative risk. As a result, the development of a risk calculator was based exclusively on UK data, with multiple co-morbidities being given additive weighting.

Clinician Demographics.

Age and sex. In all age groups, mortality was at least twice as high in men as in women (Table 1). Compared to those under the age of 50, mortality was doubled in 50-59 year-olds, quadrupled in the 60-69 years age group, and 12 times higher after the age of 70 years in men.

Ethnicity.

People of non-white ethnic origin were at a higher risk of hospitalisation and mortality than the general population. This is most accentuated in people of black African descent where the risk was two-fold elevated compared to those of white European descent. People of Indian Asian descent also had an approximately 50% increased risk of hospitalisation compared to their European counterparts. This is both when compared to the local population, and for CoViD-19 compared to non-CoViD-19 viral pneumoniae over the previous 3 years¹⁶.

Socioeconomic status. As with flu, 25% of ICU admissions are people from the most deprived quintile as evaluated compared with just 15% from the least deprived (Table 2). Once on ITU, however, there were only slight differences in mortality between people in the most deprived vs least deprived status.

Co-morbidities.

There were multiple co-morbid factors that were each incrementally associated with increased mortality. The most common recorded comorbidities are chronic cardiac disease (29%), uncomplicated diabetes (19%), chronic pulmonary disease excluding asthma (19%) and asthma (14%) (Table 2)¹⁷. These represented 16,749 patients: 7,924 (47%) patients had no documented reported comorbidity. Although numerically not a large percentage of patients, those with active malignant neoplasms and rheumatological diseases were at a 3

and 11-fold increased risk of hospitalisation respectively compared to the prevalence in the general population. Although data was sparse, there was a suggestion that other conditions requiring long term immunosuppressant therapy was similarly over-represented (data not shown). Similarly, dementia was associated with a significantly higher risk than the general population of both hospitalisation (~7.7 times increased) and mortality in hospital (39% increase). This has limited relevance for modifying clinical exposure, although may be pertinent if using this tool to assess risk within the community. Contrary to many popular media reports, there was only a marginal rise in the hospitalisation and mortality in people living with obesity, such that the composite increased risk was increased by approximately 2-fold when $BMI > 35 \text{ kg/m}^2$, but less than this had little impact..

Generating an objective risk stratification tool

By considering each of the demonstrated associated factors for CoViD-19 hospitalisation and subsequent mortality, a risk stratification tool was generated that may be considered when allocating clinical individuals to standard or higher risk duties (Table 3). The risk model attributes a point for every approximate doubling of risk compared to the reference population (Hazard Ratio ≥ 1.75 and ≤ 2.25). By adding the risk score from each category, it gives every individual a personal risk score which provides an estimate of their biological hazard.

When validating this tool against the ninety-eight predefined cases in a single NHS trust, the outcomes of the ORS tool correlated well with absolute risk scores in the OpenSafely platform (Cohen's kappa 0.71 SD 0.077; $p < 0.0001$; Table 4). A final validation was performed against the Public Health England document "Disparities in the risk and outcomes of COVID-19".¹¹ This demonstrated a similarly high level of agreement (Cohen's kappa 0.78 SD 0.068; $p < 0.0001$).

Discussion

There are currently no reliable data for CoViD-19 related deaths in health care professionals including doctors; and surprisingly few data on the differences in risk in different healthcare settings. There is an urgent need for high quality research. We have applied general

population risk factors to health care workers in order to generate a simplified biological risk stratification tool. This may serve to inform employers when allocating specific duties within the health care provision system, in order to fulfil their duty of care to their employees.

There are three types of risk for medical staff. The first relates to their biology, the second their environment and the third to the exposure. This tool evaluates the former in order to advise mitigation of the latter by stratifying individuals to lower, medium and higher risk. This biological risk assessment tool does not in any way replace the need for universal precautions with appropriate personal protective equipment. It should only be used to inform the need for modification of allocated duties to roles with little or no direct contact with patients, such as “advice and guidance” services, or virtual clinic provision. It incorporates and weights recognised risk factors. Many of these factors are predictable, such as age, gender, and pre-existing respiratory disease all of which have been associated with many previous viral infections such as H1N1 influenza.

The importance of pre-existing cardiovascular disease and cerebrovascular disease is a novel observation for a respiratory disease. This may be due to the method of cellular invasion of SARS-CoV-2 using the ACE2 enzyme; an enzyme which is responsible for physiological vascular health responses to hypertension and obesity. It does not, however, explain the risk associated with diabetes¹⁸, nor does it account for the increased risk in some ethnic groups.

A recent finding showed that Black, Asian and minority ethnic (BAME) individuals account for 63 per cent, 64 per cent and 95 per cent of deaths in the Nurse, Health Care Assistant and Doctor staff groups, respectively¹. These figures are substantially higher than the proportional increase in BAME patients in UK intensive care units (mortality of 18% compared to 12% in the general population)¹⁶. Interestingly, our tool distinguished between people of Black African descent and people of other non-European backgrounds, awarding a higher risk to those of West African descent. When validating the ORS tool against the OpenSafely report, however, the differential point award demonstrated similar overall predictive role in people of Black African descent as other ethnicities. This is likely due to different confounding disease profile in these populations. People of Indian subcontinent heritage develop additional risk factors such as diabetes and premature cardiovascular

disease approximately 10 years earlier than the European counterparts. People of Black African descent, however, are more likely to be affected by unmeasured risk factors such as haemoglobinopathies and systemic microvascular dysfunction^{19,20}.

Application of the ORS tool

The primary role of any risk stratification tool is to provide a standardised approach to individual risk management by identifying those with the greatest hazard of adverse consequences from hazards.

Once individual risk is stratified, decisions regarding mitigating actions are required. Unfortunately, there remains uncertainty regarding the best action. The impact of recurrent exposure compared to high-risk exposures with high viral load, or the environment of the clinical domain is uncertain. Likewise, the relative impact of different environments has not adequately been assessed. Currently, employees in front-line emergency and acute medical settings such as A&E medicine, anaesthesia, respiratory medicine or gastroenterology may be considered at increased risk, as may be those who may need very close proximity with the patient such as ENT and ophthalmology. Some paradoxes have been observed. One recent paper found that the rate of infection with CoViD-19 in staff in patient-facing occupations was no different from that in clerical/administrative staff without patient contact²¹ suggesting that PPE provides effective protection. Conversely, those later in the disease process with severe illness (particularly at the time of cytokine storm requiring high dependency care) may have reduced viral load and shedding²² therefore paradoxically have a lower potential to transmit infection compared to those at an early stage of the disease with no or relatively mild symptoms.

The ORS tool enables employers to decide when to exclude workers from working in presumed higher risk environments - even if workers do not wish to do so – or modify the nature of their duties, in order to fulfil the employers' legal duty of care obligations to their work force. It must be acknowledged that this tool is based purely on biological risk of an individual. The prevalence of the disease in the community is another determinant which should be considered; when prevalence is low, the increased relative risk may not reflect a significant absolute risk, allowing health care practitioners to return to their usual role.

Study limitations.

Selection bias in testing, care and reporting can lead to differences in prevalence estimates of pre-existing risk factors and presentation across the reports from various countries. The majority of the existing analyses are based on retrospective and often single-centre series. No published or completed prospective cohort studies or randomised controlled trials were present in this literature search. There is an urgent need for high quality research, using individual level data for healthcare workers that will allow full mediation analyses in order to determine whether (for example) it is the age, the diabetes, or the cardiovascular disease that actually carries the greatest prognostic risk, given that these conditions commonly co-exist, and explore the disparity in BAME individuals between the general population and the healthcare deaths. There are currently only limited observational data for CoViD-19 related deaths in health care workers or doctors, again without full access to all potentially pertinent information.

Patient and public involvement

The primary target of this research was healthcare professionals, occupational health teams and medical managers. There was significant engagement with members of the British Medical Association – the trade union representing UK doctors - CoViD group, and the staff members. Several members of this group are listed as co-authors, including the chair of the representative body. It is important to distinguish that these individuals are reporting personal views based on their branch of practice and these are not necessarily the views of the Association.

Concluding Remarks and Key Messages.

As part of an employer's legal obligation under the Health and Safety legislation all individuals are required to have a formal risk assessment. Although many organisations have advocated the need for individualised risk evaluation there remains no standardised methodology for this assessment. Without a consistent approach to stratification, comparing individuals' personal risk within a department is difficult if not impossible. We have presented a robust scoring tool that allows comparisons and thus decisions to be made

regarding the appropriate allocation of duties within a team. This also facilitates open discussion between staff who are being asked to work in patient facing areas and their team leaders, so they also understand their risks. All healthcare workers should wear appropriate PPE for any clinical examination or investigation on the basis that 20-40% of infected patients, especially if less than 40 years of age may be asymptomatic²³. Within a specialty team, the highest risk individuals should be excluded from patient facing clinical areas; those at intermediate risk should have careful consideration to exclude them from front line areas or given limited duties avoiding close contact such as in ENT, ophthalmology and dentistry. Those at the lowest risk may be assigned duties with more patient contact. Neither the ORS tool, nor any other risk score, negates the need for good personal protective equipment and training.

Contributor statement

JJ and WDS came up with the design and authored the first draft. WDS is responsible for the integrity of the analysis. All authors contributed to the format of the analysis and have contributed to the final manuscript.

Data sharing statement

This manuscript is based on a secondary analysis of published data. The analysis plan and Stata output are available on contact with WDS

Diabetes and Obesity	(Type 1 or Type 2) uncomplicated*	1
	(Type 1 or Type 2) complicated*	2
	BMI \geq 35kg/m ²	1
Cardiovascular disease	Angina, previous MI, stroke or cardiac intervention	1
	Heart failure	2
Pulmonary disease	Asthma	1
	Non-Asthma chronic pulmonary disease	2
	Either above requiring oral corticosteroids in previous year	1
Malignant neoplasm	Active malignancy	3
	Malignancy in remission	1
Rheumatological conditions	Active treated conditions	2
Immunosuppressant therapy	Any indication	2
Interpretation	Score	
Low Risk	<3	
Medium Risk	3-5	
High Risk	\geq 6	

*Complicated diabetes = presence of microvascular complications or HbA1c \geq 64mmol/mol

Table 4: Validation of the objective risk stratification tool compared to the OpenSafely Platform report. Number of healthcare workers scoring low, medium and high risk in a validation exercise of the two tools using data from 98 individuals working in the health care system.

ORS tool	OpenSafely platform report			Total number of subjects
	≤3 fold increased risk	3-6 fold increased risk	≥6 fold increased risk	
Score <3	42	2	0	44
PPV	95.5%			
Score 3-5	6	29	2	37
PPV		78.4%		
Score ≥6	0	6	11	17
PPV			64.7%	
Total	48	37	13	98

(Cohen's kappa for agreement 0.71; $p < 0.0001$)
