Decentralized governance may lead to higher infection levels and sub-optimal releases of quarantines amid the COVID-19 pandemic

Abstract

The outbreak of the novel Coronavirus (COVID-19) has lead countries worldwide to administer
quarantine policies. However, each country or state decides independently what mobility
restrictions to administer within its borders, while aiming to maximize its own citizens' welfare.
In turn, since individuals travel between countries and states, at least during periods when
quarantines are less restrictive, the policy in one country may ultimately affect the infection level
in other countries. Therefore, major questions are whether the policy dictated by a decentralized
government is efficient, and if not, how the governments can coordinate a better policy. Here,
we focus on the decision regarding the timing of releasing the quarantines. We consider a game
theory model in which each of two governments decides when to switch from a restrictive to a
non-restrictive quarantine and vice versa. We used parameter values driven by the literature and
publically available data. We show that, if travel is sufficiently frequent during the non-restrictive
quarantine periods, then the strategies are sub-optimal: Each governor tends to release the
quarantine sooner, which ultimately leads to longer periods of restrictive quarantines and a
higher prevalence of the disease. In turn, if the governments restrict international and interstate
travel to a low level even when the quarantines are non-restrictive, the policy dictated by the
decentralized governance may become optimal.

Keywords: COVID-19, dynamic games, international policy, quarantine policy

Introduction

The outbreak of the novel Coronavirus (COVID-19) necessitates quarantine policies [1-4]. While
mobility restriction measures have been taken during several disease outbreaks in history [5-11],
the quarantines needed for the COVID-19 pandemic is at a global scale that encompasses entire
countries. Such quarantines have economic and social costs [12, 13], and major relevant
questions are how restrictive the quarantines should be, and what would be the right timing to
release some of the mobility restrictions [1-3]. In practice, this decision is made independently

by multiple countries [14-16], or independently by multiple states in countries like the U.S., or
even independently by multiple municipal authorities. Each governor is expected to dictate the
strategy that best serves her/his own citizens; however, in periods when the quarantines are less
restrictive, travelers can transmit the disease between countries, sates, and cities. Consequently,
the quarantine policy in one country/state may ultimately affect the outcome in other
countries/states.

Decentralized governance has a benefit: Each country or state may have a better knowledge of
its own citizens' lifestyle and needs and may dictate a policy that better suits its own citizens.
However, the decentralized policy also comes with a cost: Each government might ignore the
cost borne to citizens of other countries due to international and interstate travel. Accordingly,
various previous game theory studies have suggested that agents (individuals and countries)
under-invest in the prevention and control of diseases [17-22].

In this paper, we examine the case where each governor decides independently about the timing
of releasing the quarantine, and we ask what the inefficiency is due to such decentralized
governance. Namely, we examine how the strategy of different governments differ from the
socially optimal strategy of a hypothetical centralized government that aims to maximize the
welfare of all the citizens in all the countries (price of anarchy). Specifically, we consider two
countries/states, and we analyze the following three cases (Fig. 1) [14-16, 23]: (1) the countries
have approximately the same population size and infection level (e.g., Italy and Spain); (2) the
countries have approximately the same population size, but one country experiences a more
severe outbreak at a given point in time (e.g., Italy and Germany); and (3) one state experiences
a more severe outbreak compared to the rest of the country (e.g., New York State vs. the rest of
the U.S.).

Model

Our model assumptions and parameterization are explicitly motivated by the COVID-19 outbreak.
We consider two states or countries, 1 and 2, and in line with concurrent data about the COPVID-
19 outbreak [4, 15, 16, 23-26], we assume that the number of infected people in each country is
very small compared to the country's total population size. Accordingly, we consider only the
dynamics of the infection level in each country, I_i, defined as the portion of individuals that are
infected in country i. (Namely, in contrast to traditional SIR models [27], here we consider shorter
timescales during which the number of susceptible individuals is constant, which is in line with
the COVID-19 data as of May 5, 2020 [4, 15, 16, 23-26]). In turn, we assume for simplicity that
each government can administer one of two types of quarantine at any given time: restrictive
and non-restrictive. Each government can choose when to switch between these two
quarantines. Specifically, we assume that under a restrictive quarantine in country i, I_i decreases

exponentially after the first two weeks at a rate $-r_0$ as long as $I_i > I_{\min}$. (Even a restrictive
quarantine is not expected to eliminate the disease entirely, and $I_{\min}$ characterizes some minimal
infection level that persists in the population.) In turn, according to evidence showing that the
infection level may still increase under non-restrictive quarantine conditions [4, 15, 16, 25, 26],
we assume that I_i increases at a rate r_i under a non-restrictive quarantine, where r_i is country-
specific and can be higher in those countries or states where interactions among individuals are
more frequent. Also, we assume that if a country is under a restrictive quarantine, there is no
travel from or to that country, whereas if two countries are both under a non-restrictive
quarantine, some individuals travel between these countries (we denote μ_{ij} as the number of
individuals that reside in country i but are in travel to country j). We describe in more detail the
dynamics of I_1 and I_2 in Methods: Dynamics of the infection levels.

In turn, the government in each country dictates the timing at which it switches from the non-
restrictive quarantine to the restrictive one and vice versa. We assume that a government will
not allow the health system in its country to collapse [1], and therefore, it will always switch to a
restrictive quarantine if I_i approaches some maximum capacity, $I_i = I_{\max}$. In turn, under this
constraint, the objective of each government is to maximize the proportion of time during which
its own citizens are under a non-restrictive quarantine. We describe in more detail the objective
functions in Methods: Objective functions.

Finally, we calculate the strategies of the governments in a Nash equilibrium (decentralized
governance), and we compare them to the socially optimal solution. In general, the Nash
equilibria in such a dynamic game depend on various assumptions about the information that
each government has, and the resulting strategies may depend on how the governments
coordinate their actions [28]. Here, we make the simplifying assumption that each government
does not get feedback about the infection level in the other country/state and decides in advance
when it releases the quarantine. In our model, this results in a unique Nash equilibrium per a
given set of parameter values (open-loop Nash equilibrium [28]). The numerical method that we
used for finding the open-loop Nash equilibria and the optimal solutions is described in Methods:
Numerical methods.

Results & Discussion

Our results show that, in all cases, if the number of travelers between the countries is greater
than a certain threshold, the governments switch to a non-restrictive quarantine sooner
compared to the socially optimal solution (Figs. 2,3). Namely, in Nash equilibrium, the governors
administer the restrictive quarantine for shorter periods compared to the socially optimal
solution, which in turn results in shorter periods before the infection level approaches its full
capacity and the restrictive quarantine is administered again (Figs. 2,3). Consequently, under

decentralized governance, the solution is sub-optimal, the total amount of time during which a
restrictive quarantine is administered is greater, and the average infection level is higher. This
result is consistent with previous results that suggested that agents under-invest in control of
diseases [17-22]. In turn, notice that in both the optimal solution and the Nash equilibrium, the
governments tend to be coordinated in the sense that the second country to switch does so when
its infection level is similar to that of the other country (Fig. 2D,F).

The difference between the optimal solution and the Nash equilibrium emerges if the number of
travelers between the authorities is above a certain threshold, in which case the price of anarchy
increases with the number of travelers (Fig. 3). On the other hand, if the number of travelers is
below the threshold, the Nash equilibrium and the optimal solution are identical (Fig. 3). This
suggests that one way to prevent the inefficiency due to the decentralized governance is to
declare in advance that travel will be restricted to a low level even when the quarantines are
non-restrictive. This may be applicable at the international scale, but much more difficult at the
municipal scale.

There are two mutually dependent reasons why decentralized governance results in releasing
the restrictive quarantine sooner. First, each governor ignores the damages that its own travelers
inflict on other countries, and thus, keeping a higher level of infection is perceived by the
governor as less costly. Second, as a consequence of the first reason, each country hosts more
infected travelers from the other country, and its own travelers are also hosted in countries with
higher infection levels. Consequently, if the infection level in a given country is low, it increases
rapidly due to travel, and therefore, it is not worthwhile for the country to reduce its infection
level beyond a certain value (where due to travel, this value may be lower than $I_{\min}$).

Finally, note that we have made numerous simplifying assumptions in our model, which suggests
various future directions for the examination of the consequences of relaxing these assumptions.
First, we considered only two types of quarantine, whereas in reality, more options are available.
In particular, governments can try to administer an intermediate level of quarantine that keeps
the infection at a constant level. Examining whether this policy is better than the ones that we
considered is beyond the scope of this paper (see [1-3]); however, it is likely that a similar result
will hold: Decentralized governance might maintain a higher infection level than the optimum.
Second, we assumed that travel is allowed under non-restrictive quarantine. However, it would
be interesting to examine policies that also dictate how to best integrate the quarantine policy
with travel policy. Specifically, further restrictions on travel might mitigate the problem (Fig. 3);
however, it should be noted that restrictions on travel come with economic cost [13]. Third, we
considered only two countries, whereas considering more countries is generally expected to
increase the price of anarchy [28]. And fourth, we considered open-loop solutions in which the
governments pre-determine their policy, but communication among the governments might lead
to the formation of agreements and coordination of a more global quarantine policy.

Figure 1: Illustration of the three case studies. (A) Both countries have the same population size and the same infection level. (B) Both countries have the same population size, but country 1 has a more severe outbreak. (C) One U.S. state is a "hotspot" and has a more severe outbreak than the rest of the U.S.

Figure 2: The equilibrium solution dictates that governments release the quarantines earlier than optimal. We consider the three cases illustrated in Fig. 1: identical countries (A, B), non-identical countries (C, D), and a state that initially has a much higher infection level than the rest of the U.S. (E, F). The left column (A, C, E) shows the optimal time for country 1 to release the quarantine, T_1^{opt}, as a function of the day when country 2 releases the quarantine, T_2 (blue line). It also shows the optimal time for country 2 to release the quarantine, T_2^{opt}, as a function of the day when country 1 releases the quarantine, T_1, on a flipped axis (mirror image, red line). The intersection of the blue and the red line indicates the open-loop Nash equilibrium. In turn, the

right column (B, D, E) shows the time evolution of the infection level in countries 1 and 2 assuming
that they adopt the Nash equilibrium strategies (I_1^{NE}, blue line, and I_2^{NE}, red line), as well as the
infection levels assuming that the countries adopt the socially optimal solution (I_1^{opt}, light blue
line, and I_2^{opt}, light red line). In all three cases, the governments release the quarantine sooner
than the optimum if they follow the Nash equilibrium. Moreover, in both the optimal solution
and the Nash equilibrium, the second country to release the quarantine does so approximately
when its infection level approaches that of the other country.

Figure 3: Travel between states may lead to inefficient quarantine policy within each state.
Demonstrated is the increase in the relative time that a restrictive quarantine is administered
(efficiency reduction) in a Nash equilibrium (decentralized government) compared to the optimal
solution. The efficiency reduction is zero if the proportion of travelers in the population (travel
rate, μ_{ij}) is below a certain threshold, and increases with μ_{ij} above that threshold.

Methods

Dynamics of the infection levels

Here we describe in detail the dynamics of $I_1(t)$ and $I_2(t)$, which characterize the proportions of
infected individuals in the populations of countries 1 and 2, respectively. Assume that each of the
two countries can be under a restrictive quarantine or a non-restrictive quarantine, and the type
of quarantine can change over time. The dynamics of I_i at time t depend on the type of
quarantine administered in both countries at that time.

<u>Option 1: Country i is under a restrictive quarantine.</u>

If country i is under a restrictive quarantine at time t, $I_i(t)$ declines at a daily rate $-r_0$, regardless
of what happens in the other country (no travel). However, there are two exceptions. First, I_i
cannot decline below a certain threshold, $I_{\min}$, characterizing the minimal level of infection in
the population. Second, if the government switches from restrictive to non-restrictive
quarantine, I_i starts to decline only after a delay of T_{delay} days. Therefore, in summary,

$$\frac{dI_i}{dt} = \begin{cases} r_0 I_i & \text{if } I_i > I_{\min} \text{ and } t_s > T_{\text{delay}} \\ 0 & \text{otherwise,} \end{cases} \tag{1}$$

163   where t_s is the time (in days) from the day when the quarantine became restrictive.

164   <u>Option 2: Country i is under a non-restrictive quarantine, but the other country, $j \neq i$, is under a</u>
165   <u>restrictive quarantine.</u>

166   In this case, there is still no travel between the countries due to the restrictive quarantine in
167   country j. Consequently, I_i grows exponentially at a daily rate r_i:

$$\frac{dI_i}{dt} = r_i I_i \ . \tag{2}$$

168   <u>Option 3: Both countries are under a non-restrictive quarantine</u>

169   In this case, individuals travel between the countries, where μ_{ij} of the residents of country i are
170   in travel to country j. If we assume that the number of travelers from a country is much smaller
171   than the number of the country's own residents ($\mu_{ij} \ll N_i$ and $\mu_{ji} \ll N_j$), it follows that

$$\frac{dI_i}{dt} = r_i I_i + \frac{r_i \mu_{ji} + r_j \mu_{ij}}{N_i} I_j \ . \tag{3}$$

Specifically, (i) the term $r_i I_i$ characterizes residents of country i that get infected inside country
i by other residents of country i; (ii) the term $r_i \mu_{ji}/N_i$ characterizes residents of country i that
get infected inside country i by residents of country j; and (iii) the term $r_j \mu_{ij}/N_i$ characterizes

residents of country i that get infected inside country j by residents of country j. Note that we
assume that travel is temporary (Lagrangian approach [29, 30]); that is, a traveler from country
1 to country 2 is still a resident of country 1 who will return to country 1, and therefore, is s/he
gets infected, it increases I_1, even the infection has occurred in country 2.

In turn, without the simplifying assumption that $\mu_{ij} \ll N_i$, Eq. (3) can be written in a more general
form:

$$\frac{dI_i}{dt} = \left[\frac{r_i(N_i - \mu_{ij})^2}{N_i - \mu_{ij} + \mu_{ji}} + \frac{r_j \mu_{ij}^2}{N_j - \mu_{ji} + \mu_{ij}} \right] \frac{1}{N_i} I_i + \left[\frac{r_i(N_i - \mu_{ij})\mu_j}{N_i - \mu_{ij} + \mu_{ji}} + \frac{r_j \mu_{ij}(N_j - \mu_{ji})}{N_j - \mu_{ji} + \mu_{ij}} \right] \frac{1}{N_i} I_j \ . \quad (4)$$

181 In our simulations, we used values of μ_{ij} that are much smaller than N_i (see Parameterization
182 subsection), and therefore, the results obtained using Eq. (3) and those obtained using Eq. (4)
183 were almost indistinguishable.

Objective functions

The government in each country chooses the time periods during which each type of quarantine
is administered in that country. We assume that the objective of each government is to maximize
the relative time during which the quarantine is non-restrictive in its country, under the
constraint that the health system does not collapse, and therefore, a restrictive quarantine has
to be administered in country i whenever I_i approaches $I_{\max}$ [1].

Specifically, denote T_i^{tot} as the time to complete a cycle during which I_i increases to $I_{\max}$ and
returns back to its initial value, $I_i(0)$. In turn, denote T_i^{non} as the total time within such a cycle
during which a non-restrictive quarantine is administered in country i. Then, we define the utility
of country i as

$$u_i = \frac{T_i^{\text{non}}}{T_i^{\text{tot}}} \ . \quad (5)$$

193 In turn, we calculate both the optimal solution and the open-loop Nash equilibrium. Specifically,
194 the optimal strategy is the one that maximizes $N_1 u_1 + N_2 u_2$. The open-loop Nash equilibrium is
195 given by the set of pre-determined strategies that are such that no country can increase its own
196 utility by unilaterally change its strategy.

Numerical methods

Since the growth rates of I_1 and I_2 are piecewise-linear, and since we considered a time delay
after the government switches to restrictive quarantine before the infection level starts to
decline, it follows from Pontryagin's maximum principle [28, 31] that the optimal strategy of each

government is to choose a time, $T_i \geq 0$, at which it switches to a restrictive quarantine and then
to wait until $I_i = I_{max}$ before switching to a restrictive quarantine again (Fig. 2).

Then, T_i^{non}, is the period from T_i until I_i approaches I_{max}, and the time during which the
quarantine is restrictive, $T_i^{tot} - T_i^{non}$, is given by the sum of three distinct periods: (i) between
$t = 0$ and $t = T_i$, (ii) T_{delay} days after I_i approaches I_{max}, and (iii) the time until I_i declines back
to its initial value, $I_i(0)$.

To find the optimal solution and the open-loop Nash equilibrium, we first generate a matrix in
which each cell characterizes a set of strategies, (T_1, T_2), and we simulate dynamics to calculate
the utility for each country in every cell. Then, the optimal solution is given by T_1 and T_2 that
correspond to the cell in which $N_1 u_1 + N_2 u_2$ is maximized. In turn, the open-loop Nash
equilibrium is found by calculating the best response of each country to every strategy of the
other country, where the intersection of the curves characterizes the Nash equilibrium (Fig. 2
A,C,E). The values of T_1 and T_2 in the matrix vary between 0 and T_{max}, where T_{max} is the time
when a restrictive quarantine reduces the infection level in both countries to I_{min}. (It is never
worthwhile to keep a restrictive quarantine for more than T_{max} days.) In turn, the size of the
matrix determines the resolution at which the strategies T_1 are T_2 are examined, and in Fig. 2,
we used a 200×200 matrix.

Parameterization

The estimations of the parameter values used for the simulation are taken from datasets and
literature related to COVID-19 [4, 15, 16, 23-26]. Notice that some parameter values vary
significantly between countries and states, and therefore, we performed sensitivity analyses to
verify that the main results are general and hold within wider parameter ranges.

Under restrictive quarantine conditions, a daily decline rate of 5% in the infection level after the
first two weeks is a reasonable estimate. For example, in China, the number of infected
individuals declined from ~86,000 to ~3,000 within 76 days, which implies $r_0 \approx -5\%$ per day.
In turn, in several countries, it took about 14-21 days before any decline occurred following a
quarantine, which suggests that considering $T_{delay} \approx 14$ days is reasonable. Next, note that r_i
depends on the restrictions used in a given non-restrictive quarantine, and it may vary between
states and countries. We used estimates that reflect the weeks before a restrictive quarantine
was administered in countries in Europe, where $5\% \leq r_i \leq 15\%$ per day is a reasonable
estimate.

In turn, we assume that I_{max} is given approximately by the infection level that was approached
in countries in Europe before the restrictive quarantine was administered or two weeks after it
was administered, where considering $I_{min} \approx 0.01\% - 0.1\%$ of the total population size is a
reasonable estimate. Next, parameters like I_{min} and the travel rates μ_{12} and μ_{21} are harder to

estimate, as they depend on the specific location and scale of the countries and state considered.
Therefore, we performed sensitivity analyses and examined a variety of values (e.g., Fig. 3).
Finally, the ratio between N_1 and N_2 reflects the relative population sizes of the two countries:
$N_1 = N_2$ characterizes the cases demonstrated in Fig. 1A,B and 2A-D, while $N_1 < N_2$
characterizes the case demonstrated in Fig. 1C and 2E-F.

Parameter values used to generate the figures

<u>Fig. 2A,B:</u> $r_0 = -5\%$ (day^{-1}), $r_1 = r_2 = 7\%$ (day^{-1}), $I_{max} = 0.1\%$, $I_{min} = 0.005\%$, $T_{delay} =$
14 (days), $N_1 = N_2 = 1$, $\mu_{12} = \mu_{21} = 0.2\% \times N_1$.

<u>Fig. 2C,D:</u> $r_0 = -5\%$ (day^{-1}), $r_1 = 9\%$ (day^{-1}), $r_2 = 7\%$ (day^{-1}), $I_{max} = 0.1\%$, $I_{min} =$
0.005%, $T_{delay} = 14$ (days), $N_1 = N_2 = 1$, $\mu_{12} = \mu_{21} = 0.25\% \times N_1$.

<u>Fig. 2E,F:</u> $r_0 = -5\%$ (day^{-1}), $r_1 = 11\%$ (day^{-1}), $r_2 = 5\%$ (day^{-1}), $I_{max} = 0.1\%$, $I_{min} =$
0.005%, $T_{delay} = 14$ (days), $N_1 = 0.3$, $N_2 = 1$, $\mu_{12} = 0.25\% \times N_1$, $\mu_{21} = 0.25\% \times N_2$.

<u>Fig. 3:</u> $\mu_{12} = \mu_{21}$ varies (x-axis), and the other parameters are the same as those in Fig. 2A,B.

Data availability

246   Some parameter values are taken from estimates in the literature [4, 15, 16, 23, 24] and some
247   are estimated from publically available datasets [25, 26] (see Method: Parameterization). All the
248   data and parameter values needed to regenerate the results shown in the figures are given in
249   Methods.
