Heising-Simons Foundation (grant no. 2019-1728), and the University of California Firearm  
Violence Research Center. The funding organizations had no role in the design and conduct of  
the study; collection, management, analysis, and interpretation of the data; preparation,  
review, or approval of the manuscript; and decision to submit the manuscript for publication.

The authors have no conflicts of interest to declare.

This manuscript is a preprint; it has not undergone external peer review. It was originally  
submitted to medRxiv on July 2, 2020; this revised version was submitted on July 10, 2020.

## KEY POINTS

**Question:** Is the coronavirus-related surge in firearm purchasing associated with changes in rates of interpersonal firearm violence?

**Findings:** This cross-sectional time series study suggests the recent increase in firearm purchases—an estimated 2.1 million excess purchases nationally between March and May 2020—is associated with a statistically significant increase in firearm violence. We estimate an increase of 776 fatal and nonfatal injuries (95% CI: 216 to 1,335) in the US over the number expected for those months had there been no increase in purchasing.

**Meaning:** During the coronavirus pandemic, an acute increase in firearm access is associated with an increase in firearm violence.

## **ABSTRACT**

**Importance.** Firearm violence is a significant public health and safety problem in the United States. A surge in firearm purchases following the onset of the coronavirus pandemic may increase rates of firearm violence.

**Objective.** To estimate the association between changes in firearm purchasing and interpersonal firearm violence during the coronavirus pandemic.

**Design.** Cross-sectional time series study. We estimate the difference between observed rates of firearm purchases and those predicted by seasonal autoregressive integrated moving average models. Using negative binomial models, we then estimate the association between excess firearm purchases and rates of interpersonal firearm violence within states, controlling for confounders.

**Setting.** The 48 contiguous states and the District of Columbia. Hawaii and Alaska are excluded due to missing or incomplete data.

**Exposure.** The difference between observed and expected rates of firearm purchases in March through May 2020, approximated by National Instant Criminal Background Check System records.

**Main Outcome and Measure.** Fatal and nonfatal injuries from interpersonal firearm violence, recorded in the Gun Violence Archive.

**Results.** We estimate that there were 2.1 million excess firearm purchases from March through May 2020—a 64.3% increase over expected volume, and an increase of 644.4 excess purchases per 100,000 population. We estimate a relative rate of death and injury from firearm violence of 1.015 (95% Confidence Interval (CI): 1.005 to 1.025) for every 100 excess purchases per 100,000, in models that incorporate variation in purchasing across states and control for effects of the pandemic common to all states. This reflects an increase of 776 fatal and nonfatal injuries (95% CI: 216 to 1,335) over the number expected had no increase in purchasing occurred.

**Conclusions and Relevance.** We find a significant increase in firearm violence in the United States associated with the coronavirus pandemic-related surge in firearm purchasing. Our findings are consistent with existing research. Firearm violence prevention strategies may be particularly important during the pandemic.

Firearm violence is among America's leading causes of death and disability<sup>1</sup> and has profound adverse social, psychological, and economic effects on life in this country.<sup>2,3</sup> A large body of research has established an association between the prevalence of firearm ownership and rates of both interpersonal and self-directed firearm violence at the population,<sup>4-6</sup> household,<sup>7,8</sup> and individual<sup>9,10</sup> levels. Surges in firearm purchasing, which acutely increase the prevalence of firearm ownership, have been well documented in association with mass shootings and significant political events and are followed by population-level increases in firearm violence.<sup>11-13</sup>

The coronavirus pandemic has created deep and widespread social and economic disruption in the United States. As of June 30, 2020, more than 2.6 million cases and nearly 123,000 deaths have been reported.<sup>14</sup> Federal Bureau of Investigation (FBI) records of background checks pursuant to firearm purchases<sup>15</sup> suggest a substantial surge in firearm purchasing in many states beginning near the onset of the coronavirus pandemic. Given prior findings, it is reasonable to expect a subsequent increase in firearm violence.

Other effects of the pandemic, or the country's response to it, might well modify the relationship between surges in firearm purchasing and firearm violence. Stay-at-home orders might reduce community violence, since fewer people are in public places—or increase it if fewer potential witnesses are on scene and/or law enforcement presence is reduced. The pandemic has exacerbated factors that contribute to interpersonal violence, including financial stress, tension, trauma, worry, and a sense of hopelessness. Fear and scapegoating associated with COVID-19 may increase hate crime. Violence at home might increase if stay-at-home

orders increase contact between persons in violent relationships, including intimate partners, children, and vulnerable elders.

In this paper, we explore the association between trends in firearm purchasing and interpersonal firearm violence during the coronavirus pandemic, relying on publicly available data: the FBI's National Instant Criminal Background Check System (NICS) records<sup>15</sup> as a proxy for firearm purchasing and public reports of firearm violence collected by the Gun Violence Archive (GVA).<sup>16</sup> We date the onset of the pandemic as January 21, 2020, when the virus was first reported in the US. Our period of observation extends through May 31, 2020.

## **METHODS**

### **Design, setting, and subjects**

This is a cross-sectional time series study of monthly firearm purchasing and firearm violence in the US from January 2018 through May 2020. The 48 contiguous US states and District of Columbia (DC) are included, resulting in 1,421 place-time units (29 months x 48 states and DC). Hawaii and Alaska are excluded due to missing or incomplete data.

### **Data sources**

We approximate firearm purchasing using monthly state-level NICS background check data<sup>15</sup> specific to firearm purchase transactions (excluding those for pawn redemptions or carry permits). Denominators for rates are obtained from the US Census' Annual Estimates of the Resident Population for states. Although NICS checks do not have a 1:1 correspondence with purchased firearms, because most states permit multiple firearm purchases in a single

transaction, this discordance is likely stable over time, leaving the data compatible with time series analyses.

GVA records of interpersonal firearm violence are based on reviews of 7,500 news outlets and other public sources.<sup>16</sup> Data used for this study include the date and location of the event and a limited set of event characteristics (Supplementary Table 1). We include only events coded as intentional, interpersonal violence with 1 or more shots fired and 1 or more persons killed or injured. We use the term ‘injuries’ to include both nonfatal injuries and deaths. GVA data have been used for research on legal intervention shootings,<sup>17</sup> firearm homicides,<sup>18</sup> mass shootings,<sup>19,20</sup> and community violence<sup>21</sup> and have performed well relative to other sources.<sup>17,19</sup>

We developed a directed acyclic graph to identify a minimum set of time-varying covariates needed to control for confounding (Supplementary Figure 1). Covariates include monthly COVID-19 cases and deaths per population, state stay-at-home orders, average monthly movement (a measure of adherence to social distancing recommendations), and average monthly temperature and precipitation. We use data on COVID-19 cases and deaths from Johns Hopkins University Center for Systems Science and Engineering.<sup>14</sup> Information on stay-at-home orders are obtained from the New York Times,<sup>22,23</sup> which maintains updated data on orders at the state level. Stay-at-home orders, which were implemented or lifted at different times, are coded as the proportion of each month that the order was in effect. Movement data are obtained from Apple’s Mobility Trends,<sup>24</sup> which compiles data on changes since January 13, 2020 in “the number of requests made to Apple Maps for directions” for various transportation

types (walking, driving, and public transportation). Data on temperature and precipitation are obtained from the PRISM Climate Group at Oregon State University (Supplementary Table 2).<sup>25</sup>

### **Statistical analyses**

Our primary exposure is the difference between observed and expected rates of firearm purchases following the onset of the pandemic. We estimate expected rates of firearm purchases for each state in March, April, and May 2020 with seasonal auto-regressive integrated moving average (SARIMA) models, in which firearm purchasing rates are estimated as a function of prior purchasing rates (auto-regressive) and forecast errors (moving average). We fit SARIMA models to training data beginning in January 2011, so as to include prior documented spikes in firearm purchasing,<sup>11–13</sup> and ending in February 2020. Models were fit using the Hyndman and Khandakar algorithm,<sup>26</sup> and residual autocorrelation was examined using the Box-Ljung test<sup>27</sup> with the Benjamini and Hochberg<sup>28</sup> correction for multiple testing.

Changes in firearm purchasing are defined as the monthly difference between observed and expected purchasing rates, beginning in March 2020 and cumulated through May (defined as 0 in all months prior to March 2020). For example, a state with 30 excess purchases per 100,000 population in March, 20 excess purchases per population in April, and 10 excess purchases per population in May would receive a value of 30 for March, 50 for April, and 60 for May. We defined the exposure this way for two reasons. First, we are able to account for variation between months, rather than averaging change across the 3-month interval. Second, we allow for the accumulation of excess purchases over time because the risks of increased purchasing may be neither immediate nor time-limited.

We estimate the association between changes in firearm purchasing and firearm violence using multivariable unconditional negative binomial regression models, which account for overdispersion and yield unbiased estimates with fixed effects.<sup>29,30</sup> The outcome is modeled as counts of injuries (nonfatal and fatal) from interpersonal firearm violence, with the log of the population as an offset.

Models include indicators for months after the purchasing spike (1 if March 2020 or later); states to control for time-invariant characteristics of states; and year and month to control for state-invariant secular and seasonal trends, including the onset of the pandemic in January 2020. We are therefore comparing within-state changes in firearm violence between states with different magnitudes of change in pandemic-related purchasing. Models include all time-varying covariates listed above and clustered standard errors to account for within-state correlation over time. We also test a quadratic term for excess purchases to assess linearity.

In addition to modeling the accumulation of excess purchases, we conduct secondary analyses to capture delayed effects by including a one-month lag of the exposure—wherein the firearm purchasing variable is coded as 0 in all months prior to April 2020.

In exploratory analyses, we examine whether the associations differ by states' baseline firearm ownership prevalence, socioeconomic status, racial residential segregation, urbanicity, violent crime rate, and social distancing, testing multiplicative interactions for each in separate models with alpha of 0.20.<sup>31</sup> Firearm ownership prevalence is measured by the proportion of suicides completed with a firearm.<sup>32,33</sup> Socioeconomic disadvantage is defined as the first principal component of each state's average high school graduation rate, percentage of adults with some college education, unemployment rate, percentage of children in poverty, income

inequality, and percentage of children living in single-parent households.<sup>34</sup> We use the dissimilarity index as an indicator for racial residential segregation.<sup>34,35</sup> Urbanicity is measured by the percentage of the population living in a rural area,<sup>36</sup> and violent crime by the number of offenses for murder and nonnegligent manslaughter, rape, robbery, and aggravated assault per population.<sup>37</sup> To account for compliance with distancing recommendations, we use Apple's Mobility Index, as described above.<sup>24</sup> Additional details about each variable and data source are in Supplementary Table 2.

Because social distancing may affect where violence takes place and how many people are at risk of injury, we also model the outcome as: 1) counts of events of firearm violence (to examine changes in events independent of the number of people injured); and 2) the ratio of injuries to events. We use a negative binomial model for the former and linear model for the latter.

We test the robustness of our findings in several ways. First, we define the exposure as the cumulative percentage change in purchasing rather than the absolute change, as the magnitude of absolute change is somewhat dependent on states' baseline purchasing rate. Second, we exclude Washington DC—which is a city, not a state—and events in which a child shot another person, as children's intent to commit violence may be unclear.<sup>38</sup> Third, we include state-specific linear trends to adjust for unmeasured confounders that are neither time nor state-invariant.<sup>39</sup> Fourth, to test whether changes in firearm violence predate changes in firearm purchasing, we include leading values of the exposure.<sup>39</sup> Finally, we add a control for changes in all-cause mortality (excluding deaths from interpersonal firearm violence and coronavirus) to capture misclassification of coronavirus deaths and broader consequences of

the pandemic on population health. Data on other causes of death, such as suicide or interpersonal violence not involving firearms, are not available.

Analyses were done with the forecast package (version 8.12) in R (version 4.0.0) and in Stata (SE 15.1). All significance tests were 2-sided and used alpha 0.05 unless otherwise noted. This study was approved by the University of California, Davis Institutional Review Board.

## RESULTS

We estimate that there were 947,788 excess purchases (95% prediction interval (PI): 705,841 to 1,189,735) in March 2020, another 550,537 excess purchases (95% PI: 247,130 to 853,944) in April, and 610,852 excess purchases (95% PI: 277,314 to 944,390) in May (Figure 1a). This represents a total of 2,109,177 excess purchases (644.4 per 100,000) over the 3-month period—a 64.3% increase over expected volume. Interpersonal firearm violence also increased nationally during this period (Figure 1b), although not above expected levels in March and April. There was a substantial increase in May, with 633 excess injuries (95% PI: 180 to 1,147) that month—a 17.7% increase over expected levels.

We find substantial variability between states in the cumulative difference between observed and expected purchasing rates during the 3-month period, ranging from -2.7 (Washington DC) to 1,454.3 (New Hampshire) per 100,000 population (average 780.9) (Supplementary Figure 2). Multivariable regression models show that changes in firearm purchasing within states are significantly associated with changes in firearm violence during this period. We estimate that an increase of 100 excess purchases per 100,000 population is associated with an increase in the rate of injuries from firearm violence (Rate Ratio (RR) 1.015;

95% Confidence Interval (CI): 1.005 to 1.025) (Table 1), controlling for effects of the pandemic common to all states. Using model predictions, we estimate an increase of 776 injuries (95% CI: 216 to 1,335) across the US from March through May 2020 over what would have been expected had no increase in purchasing occurred. This represents an increase of 7.8% (95% CI: 1.7% to 13.9%) over the 3-month period. The 1-month lagged associations are similar (Supplementary Table 3). Tests of quadratic terms provide evidence for a linear relationship.

We do not find significant variation in the association by baseline firearm ownership prevalence, socioeconomic status, racial residential segregation, urbanicity, or social distancing (data not shown). The association did, however, vary by states' baseline violent crime rate. The relationship between excess purchases and firearm violence was stronger in states with lower pre-COVID-19 rates of violent crime (Figure 2).

Findings were consistent when modeling events (rather than injuries) as the outcome (Supplementary Table 4). We find no evidence of change in the ratio of injuries to events associated with excess purchases (Supplementary Table 5).

Results were robust to defining the exposure as percentage change in purchasing (Supplementary Table 6), excluding DC and events in which children shot another person (Supplementary Table 7), and inclusion of state-specific linear trends (Supplementary Table 8) and all-cause mortality (Supplementary Table 9). Neither 3 nor 6-month leading values of the exposure—defined as the absolute change in purchasing—were associated with firearm violence (Supplementary Table 10). We did, however, find evidence of an association with 6-month, but not 3-month, leading values of the exposure when defined as the percentage change in purchasing (Supplementary Table 10).

## DISCUSSION

The results of the present study suggest a significant increase in firearm violence in the US associated with the coronavirus pandemic-related surge in firearm purchasing. We estimate a nationwide excess of 2.1 million firearm purchases in March through May 2020. States with greater increases in firearm purchasing were more likely to experience increased rates of firearm violence during this time compared to states with smaller purchasing increases, independent of other effects of the pandemic included in our models. We estimate an almost 8% increase in firearm violence in the US from March through May 2020, or 776 additional injuries, associated with purchasing spikes.

Prior studies have similarly documented an association between firearm violence and spikes in firearm purchasing related to mass shootings and political events.<sup>11-13</sup> In a study of handgun purchasing spikes in California following the 2012 presidential election and Sandy Hook shooting, every 100 excess purchases per 100,000 persons was associated with 1.044 times the rate of nonfatal firearm injuries in the year following the spike.<sup>12</sup> The magnitude of our estimate is slightly smaller (RR = 1.015)—perhaps indicative of a social distancing-induced decrease in violence in public—but we detect an association immediately following the surge.

The current increase in firearm purchases may be unique, not only in its catalyst but also in its consequences. The risks of increased firearm availability are likely compounded by the myriad effects of the coronavirus pandemic, including widespread increases in anxiety, fear, grief, economic strain, disruptions to daily routines, and racial and economic inequities.<sup>40,41</sup> The relationships seen here might not apply to surges arising under other circumstances.

This study lends support to interventions restricting access to firearms. The findings are consistent with individual- and household-level studies that have resulted in recommendations to screen for firearm ownership in healthcare settings,<sup>42</sup> support safer firearm use and storage,<sup>43</sup> and address contributing risk factors for violence.<sup>44</sup> Given the impulsive nature of most firearm violence, and the multiple strains associated with the pandemic, short-term crisis interventions, such as extreme risk protection orders and those involving violence intervention specialists, may be particularly useful during the pandemic.

Further, our findings suggest a need to address perceptions of risk and safety associated with firearm ownership. While we do not have data on people's motivations for purchasing firearms, anecdotes published in the media suggest that fears for personal safety and possible civil unrest contributed to the current surge in purchasing.<sup>45</sup> Prior to the pandemic, firearms, particularly handguns, were more commonly owned for protection against people than for other reasons.<sup>32</sup> A large and growing body of literature, including the present study, ties firearms to increased—rather than decreased—risk of firearm injury.<sup>10,46</sup> Together, these findings suggest that addressing misperceptions about the health risks and benefits of firearm ownership and improving people's sense of collective trust and security may reduce the burden of firearm violence.

## **Limitations**

We cannot infer causality from these observational data. First, though the coronavirus pandemic presents an exogenous shock, our design is subject to confounding insofar as other effects of the pandemic may influence firearm violence through pathways other than changes

in purchasing. To mitigate bias, we included all hypothesized and measurable confounders: stay-at-home orders, a measure of compliance with social distancing guidelines, coronavirus cases and deaths, and temperature and precipitation. There may be residual confounding by unmeasured or unmeasurable factors. Second, 6-month leading values of the exposure, when defined as the percentage change in purchasing, were associated with firearm violence rates. This could indicate that an increase in violence caused an increase in firearm purchasing, that the spike began before March in some states due to earlier effects of the pandemic, or that a third, confounding variable, led states with already high levels of violence to experience greater spikes in purchasing. It is unlikely that our results are explained by these mechanisms, however, because we did not observe an association in the 3 months before March 2020 or when measuring excess purchasing in absolute terms. Despite the limitations of the present study, our estimates are strong and consistent, include evidence of a linear dose-response relationship, and are plausible and consistent with the existing literature.<sup>47</sup>

There are also data limitations. GVA and NICS data provide imperfect measures of firearm violence and purchasing, respectively. To bias our results, however, there would need to be similarly-timed differential changes across states in GVA or NICS reporting. Disagreement between NICS checks and purchased firearms would most likely result from an increase in multiple-firearm transactions during surges in purchasing, which would introduce a conservative bias in estimates of the number of firearms purchased during surges. Additionally, we have no information on whether the excess firearms acquired were those used in violence. Findings from our study cannot inform relationships at the individual level.

Finally, we measure the short-term impact of changes in purchasing, and we focus narrowly on interpersonal firearm violence; effects may endure over time and extend to other types of firearm violence.

## **CONCLUSION**

We find that short-term surges in firearm purchasing associated with the coronavirus pandemic are associated with significant increases in interpersonal firearm violence. Our findings are consistent with an extensive literature that documents a link between firearm access and greater risk of firearm violence.

**Table 1. State-level association between changes in firearm purchasing and interpersonal firearm violence, 2018-2020**

	Unadjusted <sup>a</sup>			Adjusted		
	RR	95% CI		RR	95% CI	
March, 2020	1.001	0.903	1.109	0.939	0.861	1.025
Cumulative excess purchases <sup>b</sup>	1.009	1.000	1.023	1.015 <sup>g</sup>	1.005	1.025
COVID-19 cases and deaths <sup>c</sup>				1.018 <sup>h</sup>	1.009	1.028
Stay-at-home order				1.053	0.923	1.200
Movement <sup>d</sup>				1.002	0.999	1.005
Average precipitation <sup>e</sup>				0.998	0.994	1.003
Average temperature <sup>f</sup>				1.011 <sup>h</sup>	1.006	1.016

Note. Results are from negative binomial regression models with indicators for state, year, and month, and the log of the population as an offset. The outcome is counts of firearm injuries (nonfatal and fatal).

RR = rate ratio. CI = confidence interval.

<sup>a</sup> Estimates are minimally adjusted.

<sup>b</sup> Association reflects an increase of 100 purchases per 100,000 population.

<sup>c</sup> Association reflects an increase of 100 cases and deaths per 100,000 population.

<sup>d</sup> Association reflects a 1-unit increase in Apple's mobility index.

<sup>e</sup> Association reflects a 1-inch increase in average monthly precipitation.

<sup>f</sup> Association reflects a 1-degree increase in average monthly temperature, measured in degrees Fahrenheit.

<sup>g</sup> P<0.05

<sup>h</sup> P<0.001

**Figure 1. Nationwide trends in firearm purchasing (Panel A) and firearm violence (Panel B)**

**A)**

**B)**

A) Monthly firearm purchases per 100,000 population, with training data from January 2011 through February 2020. B) Monthly injuries from firearm violence per 100,000 population, with training data from January 2015 (earlier GVA data appear to reflect an undercount of events) through February 2020.

Dotted line indicates March 2020. Blue bands indicate 80% and 95% prediction intervals.

**Figure 2. Variation in association between excess firearm purchases and interpersonal firearm violence by states' baseline violent crime rate**

Note. Violent crime rate represents the average state-wide rate from 2014-2018. Rate ratios (not log-transformed) are plotted on the log scale. Wald test for interaction  $P = 0.15$ . Rate ratios reflect an increase of 100 purchases per 100,000 population at varying levels of baseline violent crime. We exclude Washington DC, an outlier with a high crime rate; this does not affect results or interpretation.
