Abstract

The global SARS-CoV-2 pandemic led to a steep increase in the need for viral detection tests worldwide. Most current tests for SARS-CoV-2 are based on RNA extraction followed by quantitative reverse-transcription PCR assays that involve a separate RNA extraction and qPCR reaction for each sample with a fixed cost and reaction time. While automation and improved logistics can increase the capacity of these tests, they cannot exceed this lower bound dictated by one extraction and reaction per sample. Multiplexed next generation sequencing (NGS) assays provide a dramatic increase in throughput, and hold the promise of richer information on viral strains and host immune response.

Here, we establish a significant improvement of existing RNA-seq detection protocols. Our workflow, ApharSeq, includes a fast and cheap RNA capture step, that is coupled to barcoding of individual samples, followed by sample-pooling prior to the reverse transcription, PCR and massively parallel sequencing. Thus, only one step is performed before pooling hundreds of barcoded samples for subsequent steps and further analysis. We characterize the quantitative aspects of the assay, and test ApharSeq on dozens of clinical samples in a robotic workflow. Our proposed workflow is estimated to reduce costs by 10-50 fold, labor by 5-100 fold, automated liquid handling by 5-10 fold, and reagent requirements by 100-1000 fold compared to existing testing methods.

Introduction

A novel Coronavirus, SARS-CoV-2, has infected almost 20 million, as of early August 2020, with more than 700,000 related deaths caused by the virus associated COVID-19¹. There is a consensus that large-scale testing is paramount for the containment of the pandemic², yet widespread testing in most countries is lacking. At the time of writing this manuscript, multiple countries are undergoing a “second wave” of infections, highlighting the need for population-level screens for prolonged durations, effectively requiring a billions of tests world-wide.

The current benchmark for SARS-CoV-2 testing is a panel of RT-qPCR tests approved by various institutions applied to nasopharyngeal swab samples³. The swabs are mixed into a lysis buffer or transport buffer and subsequently mixed with a lysis buffer, and undergo RNA extraction and RT-qPCR. Generally, in these tests, samples with cycle threshold (Ct) lower than 37 are considered positive. While this test is sensitive and specific, qualified labor and the shortage of required equipment and reagents have proven to be limiting factors at different stages of the pandemic⁴. Specifically, the testing capacity is limited since each sample is treated as a separate qPCR reaction with a fixed reaction time.

In the last decade, next generation sequencing (NGS) has replaced RT-qPCR and microarrays as the assay of choice for quantifying RNA molecules. Amidst the pandemic, different groups suggested NGS-based assays to measure the existence and abundance of the viral genome in samples^{5,6,7}. In addition to detection and quantification, these assays can provide strain-specific sequence information as events are unfolding, providing epidemiologists with data to analyze the contagion propagation through the population^{8,9}. Similarly, by assaying the RNA from host cells, aspects of the immune response in infected individuals can be unmasked¹⁰, providing potentially crucial information for patient treatment, research, and policymakers.

Here, we propose a general modification of current RNA-seq protocols that allows for pooling of barcoded samples prior to reverse transcription - Amplicon Pooling by Hybridization And RNA-Seq (ApharSeq). This improvement is especially pertinent for large scale testing as it potentially reduces the need for labor and reagents by orders of magnitude. Briefly, we show (Figure 1) that we can introduce barcoded and target-specific reverse transcription primers to the samples, allowing them to hybridize to target RNA molecules already in the lysis buffer, or after a brief RNA cleanup step. After several minutes of hybridization with the barcoded primers, we capture the sample RNA onto beads, washing away excess primers and the chaotropic lysis buffer. Importantly, the primer-RNA hybrids are preserved during this step. The bead-bound RNA is isolated, and samples are pooled to a single tube to undergo reverse transcription from the primers that remain hybridized to their targets. Finally, the pool undergoes library PCR and sequencing. Viral molecular counts per sample are determined by the sample-specific barcodes and unique molecular identifiers introduced at the very beginning of the protocol. We

demonstrate that cross-sample contamination in this workflow is negligible, and determine sensitivity to be ~450-900 copies/ml, comparable to existing approved tests¹¹.

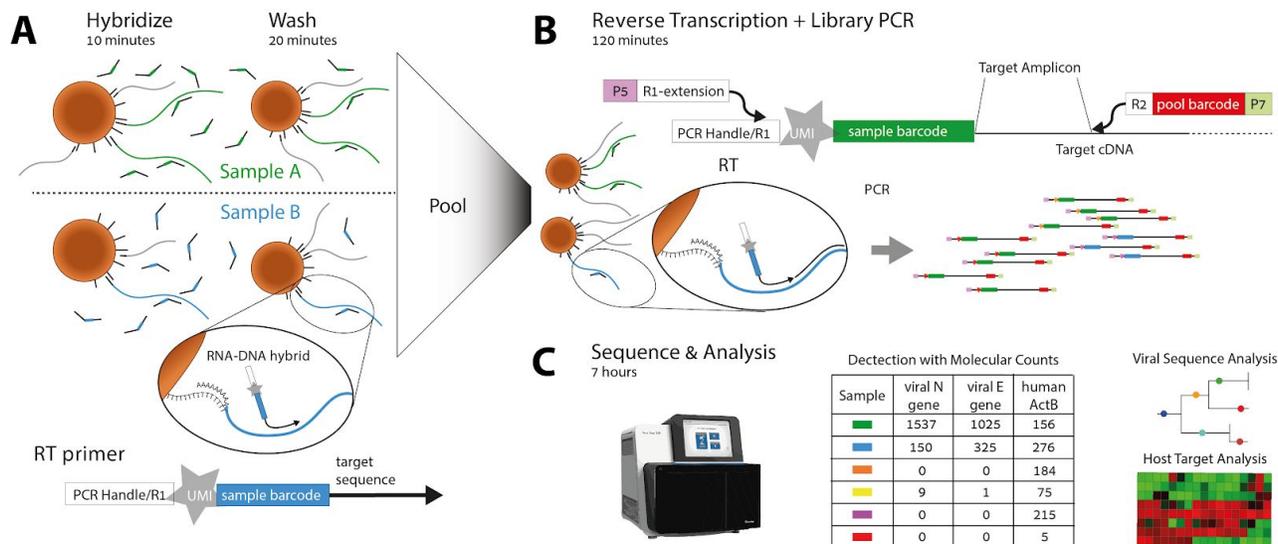

Figure 1 - ApharSeq overview

A) Barcoded and uniquely-identifiable RT primers are hybridized to samples in transport/lysis buffer for 10 minutes, paramagnetic beads are used to extract RNA and wash excess primers.

B) Beads are pooled and RNA undergoes an RT/PCR reaction with pre-hybridized target-specific primers to generate a sequencing library.

C) Libraries are sequenced and analysed, PCR duplicates are collapsed to molecular counts for detection and potentially more elaborate analyses, e.g. contact tracing by viral sequence analysis, host physiological state by mRNA analysis.

Results

A simple and quick RNA capture step

Lysis buffers contain protein denaturation and degradation reagents, typically the chaotropic guanidium thiocyanate, as well as detergents. Therefore, enzymatic reactions such as reverse transcription require RNA extraction from the lysis buffer in which the samples arrive. We tested two home-made bead-based RNA cleanup protocols, SPRI and polyT extraction¹², that are cheap, simple, amenable to automation, and take less than 30 minutes for 96 samples. In terms of RNA extraction, the performance of both approaches is within a $\pm 50\%$ range of a widely used commercial kit (see supplementary note on RNA extraction; Figure 2A; Figure S1). Preliminary tests showed that both approaches can be used for AphaSeq (Figure S1D), but we focused on the polyT-based extraction variant. Note that we do not elute the RNA from the polyT beads, rather we use the beads to capture the RNA and continue with the bead-bound material to the next step of the protocol.

Barcoded RT primers added to lysed samples prime RT reactions

We designed barcoded RT primers for the viral E gene (reverse), as it appears in the WHO panel¹³. The primer includes a 10bp barcode and a 10bp unique molecular identifier to allow for single-molecule counting¹⁴ (Figure 1A, methods). Each sample is hybridized to primers with a different barcode (Figure 1A), effectively identifying the RNA for the remainder of the protocol. The bead-bound RNA is then washed and reverse transcribed to generate sample-labeled cDNA.

To evaluate the efficacy of primer-RNA hybrid formation and stability through the cleanup stage, we designed a qPCR reaction targeting the generic PCR handle on the RT primer and the amplicon target sequence. This assay allows us to quantify the number of hybrids that survive the washes and succeed in generating a cDNA molecule. Using the qPCR assay, we established that RT primers indeed remain hybridized during the RNA extraction and initiate reverse transcription reactions (Figure S2). Furthermore, we used this simple assay to run several optimizations for the first steps of the protocol and improve the yield significantly (Figure S2).

Sequencing library preparation

The next step in the AphaSeq protocol is to generate sequencing libraries. This is achieved in a single PCR step, amplifying the RT primer from the generic sequencing handle and from the forward amplicon-specific primer,

extending the amplicon with Illumina-compatible handles (Figure 1B). When we applied this PCR to positive and negative samples we consistently obtained amplicon-specific libraries only in SARS-CoV-2-positive samples (Figure 2B). When sequenced on a next generation sequencing platform, these libraries yield highly specific results with >95% of reads aligning to expected viral target sequence in positive samples (Figure 2C). Importantly, sequencing the insert provides direct evidence for the presence of the virus in samples, bolstering confidence in the assay's results. Observing the target sequence directly allowed us to identify viral sequence variations in some cases (Figure 2D). Cross-Sample Contamination is minimal

When pooling samples early on in the protocol, the main concern is that RNA molecules will be erroneously tagged due to residual free primers, or due to other artifacts during RT, PCR, or sequencing. To test cross-contamination levels in the RT stage, we hybridized positive (Ct 26) and negative samples with two differently barcoded primers, pooled them, performed RT and tested the amount of cross-contamination by barcode-specific qPCR (Figure 3A and 3B). We find that the pooled negative sample is indistinguishable from the unpooled negative sample, suggesting cross contamination is negligible.

Next, we examined potential cross-contamination during PCR or sequencing¹⁵. We subjected four samples - Ct18, Ct33, and two negative controls (ddw) to AphaSeq. We hybridized the barcoded primers, and then pooled the samples prior to RT and PCR (Figure 3C). Again, we find that barcodes that were hybridized to negative samples have at least 50,000-fold less reads than those that were hybridized to the high Ct positive sample. These results are not unique to the polyT-based capture, and were qualitatively replicated using SPRI-based RNA cleanup (Fig S1D). We conclude that cross-sample contamination is a minor issue in AphaSeq.

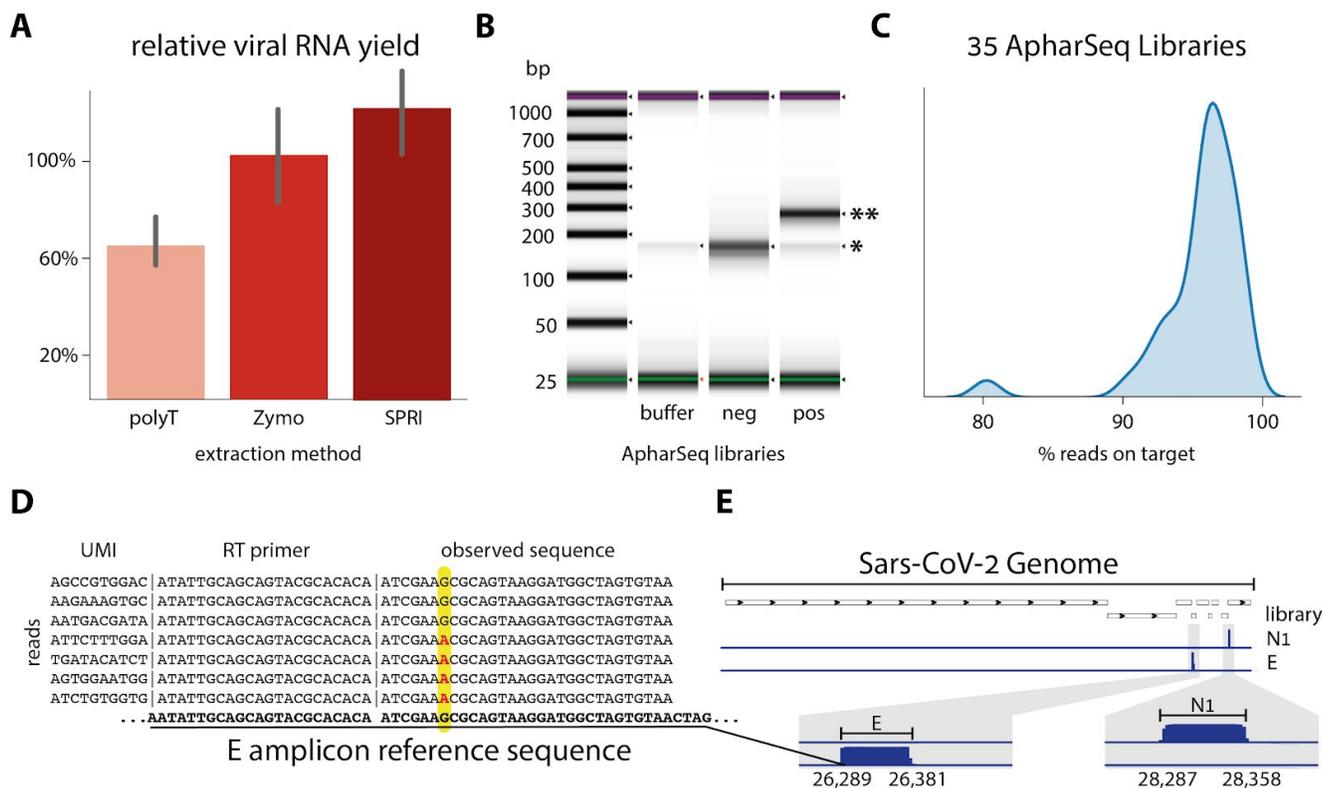

Figure 2: The ApharSeq pipeline generates specific sequencing libraries.

A) RNA capture by homemade polyT and SPRI paramagnetic beads is efficient (~60-120% compared to Zymo kit), and quick (<30' for a 96 plate on a robotic system). See supplementary note on RNA extraction.

B) Sequencing libraries of the viral envelope amplicon (E) are specific to positive samples (* primer dimer, ** expected amplicon: 269 bp).

C) Libraries are highly specific: >75% of libraries have more than 95% of reads mapped to the expected sequence.

D) Observed sequences conform to the reference genome in >99.9% of reads (not shown). However, in at least one sample we observe a sequence variation in reads from the E amplicon at 26,353 (G to A). Observed SNP is in more than 90% of reads of each UMI shown (~200 reads each), excluding the possibility of sequencing errors.

E) Genome browser view of N1 and E amplicon libraries highlight target specificity

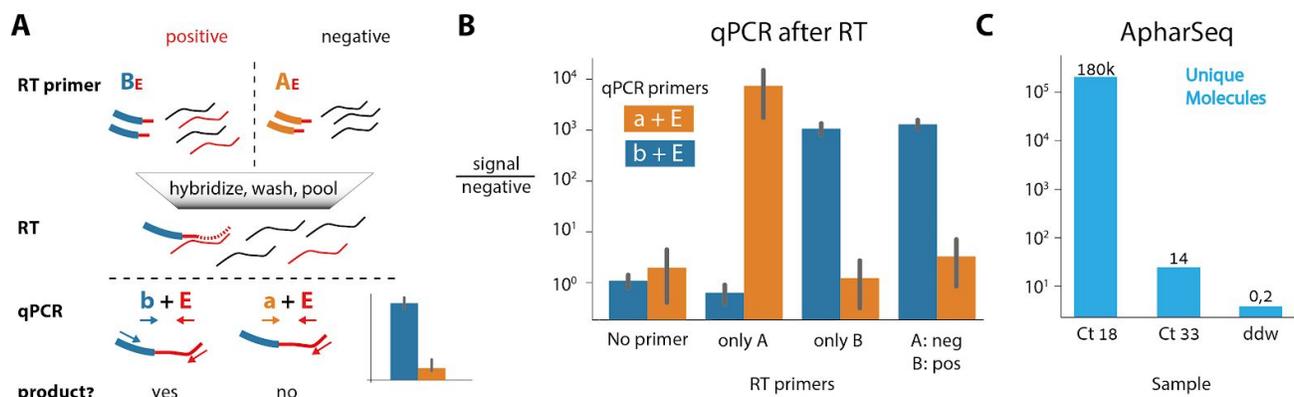

Figure 3: Minimal Cross-contamination in ApharSeq.

A) qPCR cross-contamination assay - Different RT primers (uppercase AE/BE) targeting the same locus (viral E amplicon) are hybridized to a positive/negative sample, then samples are pooled, reverse transcribed, and RT-primer-specific qPCR primers (lower case a/b) are used in qPCR to detect successful RT reactions on the viral target.

B) qPCR results in fold change relative to no template control.

C) Minimal cross contamination test in ApharSeq libraries as quantified by unique molecules detected in a pool of four samples with Ct 18, Ct 33 and two negative controls. Numbers above the bars are the counts of unique molecules in each sample.

ApharSeq is quantitative and sensitive

To evaluate the dynamic range of ApharSeq, we titrated a positive sample into lysis buffer and generated samples that span the Ct range ~23-31 in 320 μ l. We applied ApharSeq to these samples in a pool and as individual samples (Figure 4A). We find that the number of unique molecules scales linearly with the input (p-value < 0.001; Figure 4B). Accounting for observed background in negative samples, we predict the limit of detection to be ~Ct 35.7. Importantly, the linear titration curve in the case of the pooled samples highlights the minimal interaction and contamination between pooled samples.

We next tested the limit of detection directly, by performing another pooled titration experiment with highly diluted samples with Ct range 30-42 (Figure 4C), while adding a quantified reference (methods). Using these quantified controls, we estimate the end-to-end capture rate of ApharSeq at ~1.5% (observed 33 and 14 molecules out of an input of ~2000 and ~1000 molecules, respectively). Similarly, we could also calibrate the titration curve from Ct units to molecular counts, and found the limit of detection to be 450-900 molecules/ml, depending on sequencing depth (Figure 4D), threshold selection, and input volume used (methods).

Multiple Target Assay

A major advantage of sequencing-based assays is the capacity to capture and readout a large number of targets from the same sample¹⁶. As a first step towards a multi-target assay, we aimed at multiplexing two targets. We started by designing RT and PCR primers for the viral N1 amplicon, as it appears in the CDC panel¹⁷, and used it in conjunction with the E amplicon RT and PCR primers. We applied ApharSeq to a positive sample with each primer separately or with both primers together (Figure 5A). The results of individual and multiplexed amplicons are almost identical (Figure 5B), suggesting that the viral targets are largely independent and can be probed simultaneously to improve confidence, and potentially improve sensitivity. Notably, the N1 amplicon yields roughly 2-3 fold more molecules, consistent with previous reports¹⁸.

Next, as an internal control, we designed primers for several human transcripts with varying expression levels¹⁹ and after a preliminary test (Figure 5C, Figure S3) we decided to continue with a β -Actin amplicon as it is also used in an approved detection kit²⁰. Subjecting positive and negative samples to the ApharSeq pipeline with primers targeting viral E and human ActB amplicons produced sequencing libraries, albeit with slightly reduced yields (Figure 5D). Importantly, qPCR tests on mixed libraries showed that titration of the human-specific primer in the PCR affects the human/viral amplicon ratio accordingly, allowing for calibration of the number of reads allocated to each target in a multi-target library (Figure S3).

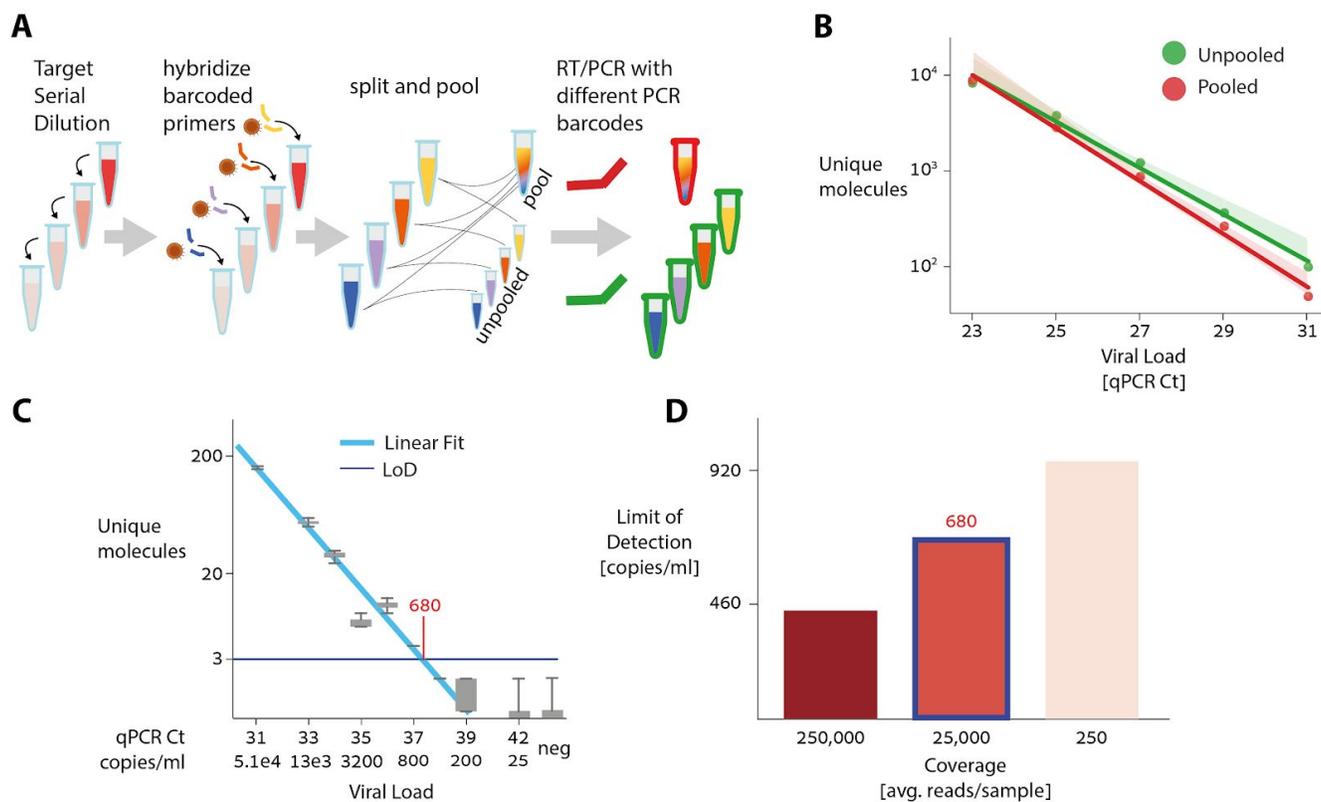

Figure 4: ApharSeq Sensitivity.

A) Target titration experimental scheme. SARS-CoV-2 positive sample is diluted in lysis buffer. Diluted samples are hybridized to barcoded ApharSeq primers (interior tube color), and split so they can be assayed separately or pooled. Samples are subjected to PCR with different barcodes (red/green) to distinguish their treatments.

B) Assay is linear in both cases (p value < 0.001). The linearly extrapolated LoD for pooled samples is \sim Ct 35.7 and is 4 times lower than the LoD for the single samples (methods).

C) Low target titration experiment, in which we also introduced a viral target control for quantification (methods) shows the actual LoD is \sim 680 molecules/ml (Ct \sim 37.4).

D) Limit of detection as a function of Sequencing Depth as derived by down-sampling the sequencing reads (methods). Highlighted bar (\sim 25,000 reads per sample) corresponds to data in C.

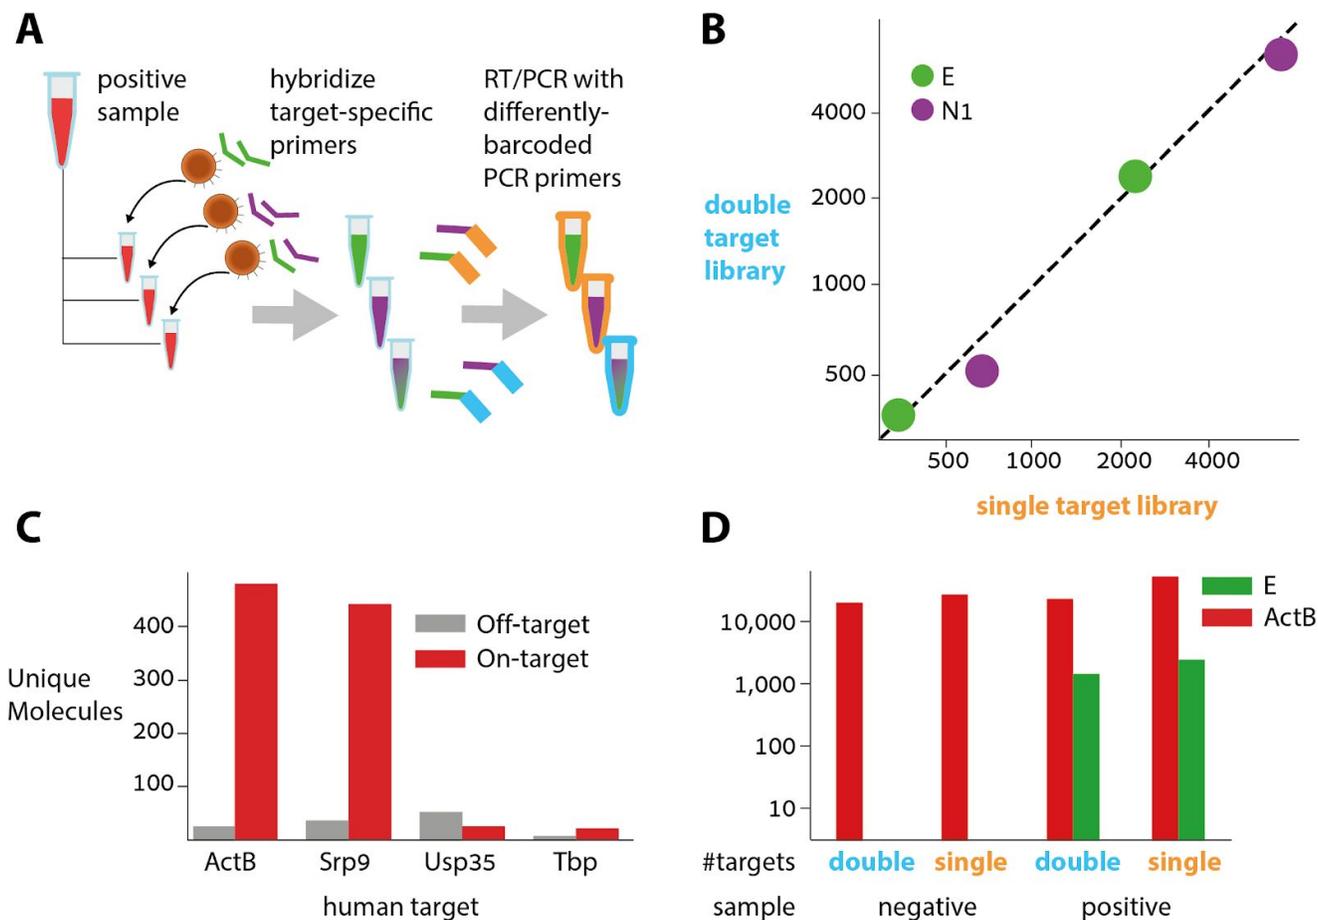

Figure 5: Multi-target ApharSeq libraries.

A) Multiple target assay scheme. A positive sample was split and hybridized with E, N1, or E+N1 RT primers. These samples underwent ApharSeq with differently-barcoded PCR primers to delineate reads from the double/single hybridization conditions.

B) Target Multiplexing Results. ApharSeq libraries for high/medium viral load samples for the N1 and E amplicon separately (x-axis) yield similar counts to a single ApharSeq library for both targets (y-axis). Units are unique molecular counts.

C) Human Target Tests for multiple genes on a pool of negative samples highlights potential specific targets at different expression levels (see all targets tested in figure S3).

D) Human and viral targets multiplexed in the same ApharSeq library (“double”) allow for internal control in negative/positive samples. Units are unique molecular counts.

Robotic AphaSeq on clinical samples

Finally, we wanted to validate that AphaSeq can scale to hundreds of samples. To this end we developed and tested a robotic protocol on a Tecan liquid handling station. With our current preliminary protocol, a single 96 sample plate is processed in 30 minutes, and then can be pooled to a single tube for RT-PCR.

To test AphaSeq in a real setting we obtained RT-qPCR positive samples (Ct 23.1, 24.6, and 26.7), and dozens of negative samples from the clinic. We diluted each positive sample twice to different levels for a total of six positive samples ranging from Ct 26 to 31. We randomly arranged these samples in a plate, along with various controls (Figure 6A). We subjected the plated samples to our robotic AphaSeq protocol and sequenced the resulting libraries. We obtained hundreds-thousands of unique molecules from the human ActB primers in all negative and positive samples. Unexpectedly, we see ActB reads in the ddw controls (an order of magnitude less than in samples). This is most likely due to primer contaminations in the original primer plate we discovered later (see supplementary note on contaminations). When examining the N1 amplicon in the 90 negative samples (19/36/35 with no-primer/ddw/negative sample respectively) we observe no reads at all, except for two samples that yielded 2 and 31 reads. Extrapolating from the positive samples, 31 reads correspond to ~Ct 38, i.e. it is conceivable that this is a positive sample that was undetected in the standard PCR test. On the other hand, 5/6 of the positive samples yielded thousands of viral N1 reads each, clearly separating positive from negative samples. The one positive sample that yielded no viral reads at all was diluted twice and did yield many N1 reads in the other instance. We therefore suspect that we made an error during sample preparation, and this is not a false negative instance.

Overall, we conclude that the robotic protocol works efficiently, with minimal to none cross-sample contamination, and we can clearly separate positive from negative samples.

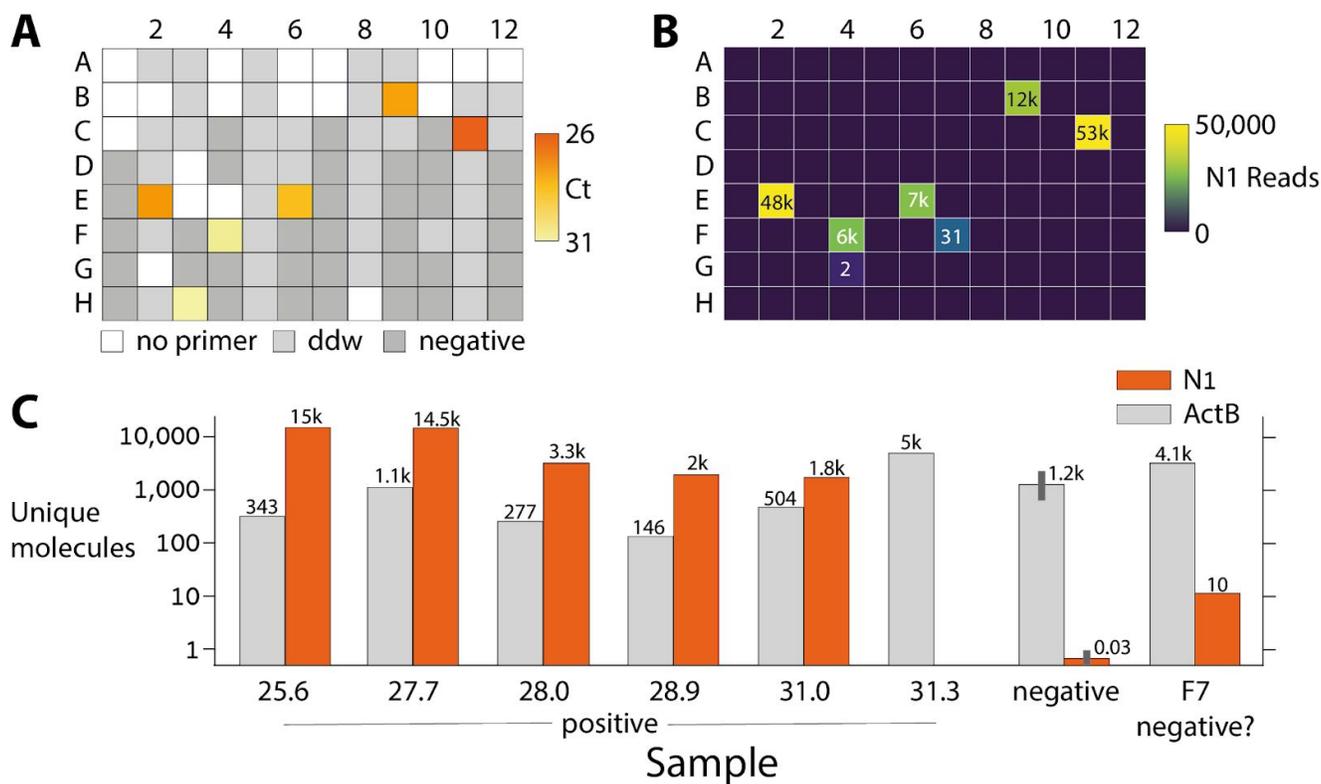

Figure 6: Robotic test of clinical samples

A) Plate scheme. A plate was prepared with six positive samples (diluted from three clinical positive samples), and 90 negative samples of various kinds.

B) Viral N1 reads. Numbers of reads shown per well in the plate (where no number appears we saw no reads).

C) Summary of results. Unique molecules observed in samples for the N1 and ActB amplicons. Numbers above the bars are the counts of unique molecules in each sample (or the average over the group of negative samples).

Prospects for massive testing

The results presented in this manuscript establish the AphaSeq pipeline as a SARS-CoV-2 detection test. We believe that AphaSeq is uniquely poised to allow tests at a massive scale, for both the low cost and minimal labor it requires.

The cost for a single test is currently between 2\$-4\$ (when processing 8000-1000 samples, see supplementary note on costs), and the bulk of the costs are due to primer synthesis and beads (50%) and consumable plastics (tips, plates, etc, 30%). These prices can probably be reduced by a factor of 10-20 when the process is streamlined, and reagents are manufactured and purchased in bulk.

In terms of labor, the bottleneck is the first step that involves per-test hybridization and washes. While this can be performed manually in roughly 45' for 96 samples with a multichannel pipette, the optimal setup includes an automated liquid handling station, in which case this step requires 20-40 minutes, depending on the sample volume tested and the specifics of the robotic setup.

The sequencing requirement for the test is reading a single pool barcode (8 bp) and at least 50 bases from read1 or 20 bp from read1 and 30 bp from read2. When we down-sampled the data in the titration experiment, we found that a change of x1000 in sequencing depth only incurs a 2-fold reduction in sensitivity. Additionally, using the Ct distribution observed in the clinic, we performed a simulation to estimate the false positive and false negative rate as a function of sequencing depth (Figure S5). In these simulations, when sequencing depth ranged from 10,000 to 100,000 reads per sample the false negative rate ranged from 4.5% to 0.2% respectively. We conclude that 50,000 reads per sample on average should suffice (Figure 4D, figure S5), especially considering that most samples are negative and “consume” much less sequencing reads (from the human target only). This means that a single NextSeq run with 400×10^6 reads suffices for processing ~8,000 samples, and a NovaSeq S2 100bp run with 8×10^9 reads for processing ~160,000 samples.

While highly informative and rich, the main drawbacks of sequencing-based assays are twofold - the requirement for specialized and expensive equipment, and the slow generation of data (e.g. a NextSeq 55bp run requires ~6.5 hours). While a 12-18 hour turnaround time is probably prohibitive for emergency testing, we believe that for large scale and routine population screens it is reasonable. Further, there are potential optimizations and workarounds that can reduce the sequencing runtime by a factor of 2-3²¹.

Importantly, we have preliminary results (not shown) that pooled RNA can be maintained for at least 24 hours in a standard RNA preserving buffer, and therefore samples can be processed in different facilities and collected to a central sequencing site for the last steps of the protocol (Figure 7).

Since the main equipment required for the application of ApharSeq already exists in many diagnostic facilities, we envision a gradual transition from the qPCR technology to sequencing-based assays by partial re-purposing of labs. For example, a facility with five liquid handlers can process upto ~2000 samples in two hours¹², and then get back to its usual testing qPCR program. The pools generated during these two hours from four such facilities can be collected to a central sequencing center.

Once such advancements are made and ApharSeq proves useful and informative it can be used as an alternative avenue in case of supply shortages, or diversify the types of tests a single facility can provide for different use cases, namely high-throughput non-urgent population screens vs. lower-throughput urgent testing.

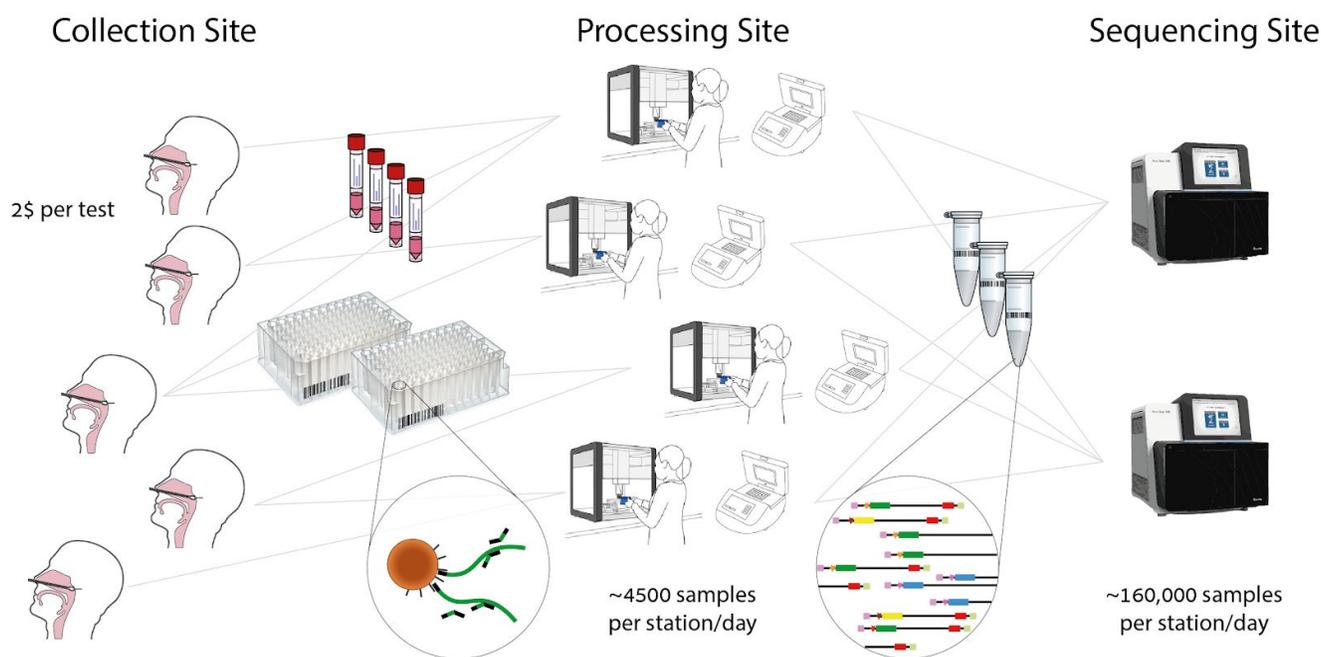

Figure 7: High Throughput testing at less than 2\$ per test.

We propose a division of labor scheme where any facility that has an automated liquid handler and a PCR block can function as a first step in the processing pipeline. A single 96 plate is processed and pooled every ~30 minutes in every such station. These pooled batches can be collected to a central sequencing facility that pools them further for cost-effective sequencing.

If collection into plates is not feasible, there are dedicated automated liquid handler stations for re-organizing tubes into plates, as is already the case in most testing facilities.

Discussion

Here we propose AphaSeq, an early-pooling protocol for the detection of the SARS-CoV-2 virus in clinical samples using next generation sequencing. While sensitive RT-qPCR assays are the backbone of testing in the current pandemic, they are lacking sequence information that may be crucial to trace infection chains, and more importantly, they are difficult to scale up.

The current second wave of infections highlights that global testing and tracing efforts require an orders-of-magnitude scale-up. We believe that our approach, and future improvements and modifications thereof, might form the basis for such an improvement of several orders of magnitude relative to current testing strategies. Specifically, the ability to pool hundreds or thousands of samples as early as possible, without losing the sample-specific information, is a crucial improvement on all currently published NGS-based tests^{6,22,23,24,25,26}. The early pooling approach proposed here, which might be applicable to other protocols, elicits proportional reductions in costs and labor that directly translate to higher throughput in testing.

While we established key properties of our approach, namely linearity, high-sensitivity, low cross-reactivity, and the potential for multi-target testing, there's still much to be done. Specifically, more optimization can improve efficiencies, shorten durations, reduce background noise and increase the sensitivity. Similarly, it is straightforward to introduce multiple internal synthetic controls that will provide clinicians with reproducible and informative assay measures and reliable results⁷.

Once the detection hurdle is surpassed and the relevant infrastructure and logistics are set into place, AphaSeq should be easy to extend to other more advanced applications in the context of the disease. Testing for co-morbid or confounding pathogens like the flu, amplifying viral variable regions to identify infection chains^{27,28}, and monitoring the host immune response with key transcripts²⁹ are just some of the potential applications of our generic approach. While these will incur some additional costs, we believe that for many applications the benefits will significantly outweigh the costs.

Finally, we want to note that the approach developed and validated here - hybridization of barcoded primers followed by early pooling - is of a general nature and can potentially be used to enhance existing protocols, including single cell and bulk RNA-seq protocols.

Methods

RNA extraction benchmarking

Viral RNA was extracted from an in-vitro grown virus (Ct ~14) and serially diluted 1:25 in a negative sample. Each dilution was subjected to RNA extraction in three methods:

1. 400 μ l sample with Quick-RNA MagBead (Zymo research), according to manufacturer's instructions
2. 400 μ l sample following the polyT extraction described below
3. SPRI-based extraction as published¹² with modified volumes: 152 μ l sample, 51 μ l beads, 153 μ l PEG buffer, 122 μ l binding buffer

For all extractions, the titration curves were linear (not shown). Samples in the linear range were corrected for their dilution and collated to estimate the mean relative yield and error for each extraction method (Figure 2A).

Primer Design

All oligos used in this study are provided in a supplementary excel spreadsheet.

RT primers

RT primers consist of four main parts - from 5' to 3' - a general illumina handle (nextera R1), a 10 bp unique molecular identifier, a 10bp barcode, and a target-specific primer. After the first iteration of sequencing experiments, we decided to: a) interleave the UMI (U) and barcode (B), to avoid long stretches of the same nucleotide in the UMI sequence, and b) add to each primer a variable sequence of 0-2 N's prior to the amplicon primer, to increase sequence complexity in each machine cycle:

- Nextera R1 sequence handle - **GCGTCAGATGTGTATAAGAGACAG**
- UMI/Barcode - **UUUUBBBBBUUUUBBBBBUU**
- Offset - **N{0,2}**
- Target primer -

- N1 **tctggttactgccagttgaatctg**
- E **atattgcagcagtagcacaca**
- ActB **acagcctggatagcaacg**

Example of a specific primer (c410 - ActB RT primer):

CGGTCAGATGTGTATAAGAGACAGNNNNACCTCNNNNATCANNNacagcctggatagcaacg

PCR primers

There are two different PCR strategies we employed during the development process - one-step and two-step PCR. The two step PCR is composed of a first step that amplifies the target molecules with an extendable handle, and in the second step barcode and the remaining Illumina sequences are introduced. The one-step reaction performs everything in a single reaction with a single long primer (~90 bp). A one-step reaction is more convenient, and is less prone to contaminations (see supplementary note on contaminations), however, it's less modular. Specifically - the long primer contains a target specific sequence and a barcode, which means that a barcoded primer collection must be synthesized per target. The two step PCR decouples this dependency, which means that a single collection of barcoded primers can be used on any target, assuming a simple target-specific primer is used in the first step. Both approaches yielded similar results, and we are currently using the single-step reaction to avoid contaminations.

One-step PCR reaction

The PCR amplifies the generic handle on the RT primer on one side, and a target-specific sequence on the other side. Additionally, the PCR extends the amplicons to a sequencing library by adding the relevant flanking Illumina sequences. Including an 8bp barcode that marks the pool of samples amplified in the PCR reaction:

Reverse primer (generic):

CAAGCAGAAGACGGCATAACGAGATGTGACTGGAGTTCAGACGTGTGCTCTTCCGATCT

Forward primer (target-specific, and **indexed**)

- N1 gacccccaaatcagcgaaa
- E acaggtacgttaatagttaatagcgt
- ActB caccaactgggacgacat

An example (c418 - ActB PCR primer):

CAAGCAGAAGACGGCATAACGAGAT**TCGGACTA**GTGACTGGAGTTCAGACGTGTGCTCTTCCGATCTcaccaac
tgggacgacat

Two-step PCR reaction

The first step adds a target-specific handle on the forward side, and extends the generic handle in the reverse (RT) side of the amplicon. We do this with the Tn5-Rd1/Rd2 published (Illumina FC-121-1030) sequences:

Reverse primer (generic):

TCGTCGGCAGCGTCAGATGTGTATAAGAGACAG

Forward primer (B6 - N1 PCR primer):

GTCTCGTGGGCTCGGAGATGTGTATAAGAGACAGgacccccaaatcagcga

The second PCR step extends the handles to a complete library with the Ad1.x and Ad2.x indexed primers as published³⁰.

ApharSeq Protocol

The detailed and complete protocol was published separately³¹. For convenience we briefly describe the protocol below. Since the protocol stabilized with time, some experiments are slightly modified relative to the current protocol. The supplementary material contains a list of experimental modifications per experiment shown indexed by figure panel.

Bead Preparation

We tested commercially available polyT beads (ThermoFisher dynabeads cat# 61002), or conjugated carboxylate coated beads (GE healthcare Sera-Mag SpeedBeads cat# 65152105050250), and followed the manufacturer conjugation protocol.

Hybridization and RNA purification

Option 1: Purification and hybridization on PolyT beads

This RNA purification protocol is based on a protocol for rapid isolation of mRNA³² with some modifications. Briefly, polyT conjugated beads were washed once and resuspended in binding buffer. The resuspended beads were mixed 1:1 with the sample. After a hybridization period of 10 minutes at room temperature with periodic mixing, the supernatant is removed and the beads are resuspended in a 50 μ l 1:1 mix of binding buffer and 10 μ M barcoded RT primers. To denature RNA secondary structures, the samples were incubated at 72C for 2 minutes and immediately transferred to ice for at least 2 minutes. Samples were then incubated at room temperature for 10 minutes with periodic mixing to allow hybridization of RNA to the beads and to RT primers. Beads were resuspended in 450 μ l wash buffer A and magnetized. Majority (380 μ l) of the supernatant was removed and beads were resuspended in the remaining 70 μ l of buffer A, and pooled. After pooling samples are washed once in buffer A, twice in buffer B, and can then be kept in RNA later until they are processed further. Preliminary tests show that RNA can be stored on the beads, in RNA later at 4C, for at least a week.

Option 2: Purification and hybridization on SPRI beads

RNA extraction with SPRI beads, followed our published protocol for RNA extraction¹² with several modifications. Samples in lysis/transfer buffer were mixed with barcoded RT primers, then incubated at 72C for 2 minutes and immediately transferred to ice for at least 2 minutes. Samples were then mixed 1:1 with binding buffer (as above) and incubated at room temperature for 10 minutes with periodic mixing to allow primer hybridization. Next, samples were mixed 1:0.8 with home-made SPRI beads in PEG buffer¹². Beads were washed twice with freshly made Ethanol 80%, air dried, and eluted in

DDW. This was followed by a second 0.8x SPRI cleanup to ensure the removal of any excess primers. At this stage samples were pooled to a PCR tube to undergo RT and PCR.

cDNA synthesis and Library preparation

The pooled beads were washed once with 1xRT buffer and RT reaction was performed with SmartScribe enzyme (SMARTScribe Reverse Transcriptase, Takara Bio) at 42C for one hour followed by incubation at 70C for 15 minutes. To elute the cDNA from the beads, the samples were incubated at 98C for 2 minutes, magnetized and the supernatant was transferred to a new tube and cleaned by SPRI beads x2 (Agencourt AMPure XP, Beckman Coulter). NGS sequences were added by PCR (KAPA HiFi HotStart ReadyMix, Kapa Biosystems, 30 cycles), and the DNA was purified using 2x SPRI beads.

NGS data analysis

Reads were demultiplexed using `bc12fastq` (version 2.20.0) and further processed by ad-hoc python scripts that are available as jupyter notebooks. We used the python API of UMI-tools to cluster UMI sequences. Specifically the “directional” option with the edit distance threshold set to three³³

Quantifying target molecules

To generate a quantitative polyA viral reference, we extracted RNA from a clinical sample and estimated the amount of molecules in this RNA extract to be 6000 molecules/ μ l using a synthetic viral sequence (Twist Bioscience SARS-CoV-2 RNA, MN908947.3) as a reference in a standard RT-PCR kit. We loaded two samples with 10 and 5 μ l of this reference RNA in a total of 320 μ l lysis buffer, and applied the AphaSeq protocol. Only 1/30 of the material underwent library preparation, which means that at most, we expect to see 2000, or 1000 molecules in the 10, 5 μ l samples respectively. After UMI clustering we observe 33 and 14 molecules respectively, suggesting that we capture ~1.5% of molecules. In the same experiment, a sample corresponding to cycle 29.3 had a similar UMI count (32 molecules), allowing us to roughly calibrate the Ct units to target molecules / ml at Ct 29.3 = $6150 \times 10 / 0.32 = \pm 190,000$ molecules/ml. This number is much higher than the numbers reported in other publications (for example Ct 33.5 = 200 i.e. Ct 29.3 < 3500). If true, this means the LoD of our assay is actually *lower* than reported in this manuscript.

Limit of detection determination

For the high load titration (Figure 4B), a linear fit (python `scipy.stats.linregress`) was performed:

$$y \sim b + ax$$

Where y is the $\log_{10}(\#UMIs)$ and x is the calculated Ct of the sample. Given this linear fit, we can extrapolate to the UMI detection threshold, which in this case was set to 3 (a conservative estimate). The fit statistics are:

statistic	singles	pooled
Slope (a)	-0.242	-0.276
Intercept (b)	9.55	10.3
p-value	2.86e-4	2.53e-4
R ²	0.99	0.99
Ct @ $\log_{10}(3)$	37.48	35.7

For the low load titration (Figure 4C and 4D), we perform re-sampling of the data (x500 times):

For factor in (1, 3, 10, 30, 100, 300, 1000):

For each sample

For each UMI in sample

$$\#sampled-reads(UMI) \leftarrow \text{Poisson}(\#reads(UMI) / \text{factor})$$

We then count the number of UMIs per (sample, factor, replicate) as the number of UMIs with $\#sampled-reads(UMI) > 0$. Given these counts, we set the detection threshold as the minimal number of UMIs that is above 99% of replicates in the negative samples. Therefore this number varies with sequencing depth and the UMI background in the negative samples. We fit each sampled replicate of the data with a Poisson-noised exponent:

$$y \sim \text{Poisson}(2^{b-ax})$$

Where y is the number of observed UMIs and x is the calculated Ct of the sample. We then set the LoD per factor to be the maximal Ct such that 95% of replicates is above the LoD.

resampling factor	Avg. #reads per sample	UMI threshold	LoD [Ct]
x1	247.7k	3	38.0
x3	82.6k	3	37.8
x10	24.7k	3	37.4
x30	8.26k	3	37.2
x100	2.47k	3	36.9
x300	826	2	37.2
x1000	248	2	36.8
