Abstract :

Introduction: Steroids have theoretically seems useful in critically ill patients of COVID-19 . However the time of starting steroid and dose remains a matter of concern due to still emerging evidences and wide-ranging concerns of benefits and harms. We did a retrospective record analysis in an apex teaching hospital ICU setting to explore this concern.

Methodology:

45 adults age ≥18 years with nasopharyngeal swab PCR-confirmed SARS-CoV-2 infection with ARDS admitted to ICU in between 20th March,2020 to 15th July 2020 were included in chart review. We did a bivariate analysis of age ,comorbidity, infections, severity of disease , timing /dose(appropriate) steroid and presence of infection on survival. In the next step we performed a Bayesian Exact regression to understand the adjusted effect of early appropriate steroid on survival in the presence of age and infections as probable confounder.

Results: Bivariate analysis showed the statistically significant effect of age <60 years and steroid dose (early and classified by disease severity) had a favourable effect on outcome. Further Early Pulse Steroid (EPS) amongst the more severe subgroup was found to be significantly associated with better survival.

Conclusion: High dose steroids (≥500 mg MPS) if given early in the course of disease to COVID19 critically ill patients (P/F<150) can significantly reduce mortality and are not associated with increased infections.

Introduction

Since the start of COVID19 pandemic, multiple repurposed drugs like antivirals [Hydroxycholoroquine, Remdesivir] , anti-inflammatory (steroids, Tocilizumab or anakinra), anticoagulants and fibrinolytics have been used with variable success.[1,2] As the pathophysiological pathways around COVID-19 are still advancing in the light of new acquired evidences, one may witness the differential standardized protocols adopted in different settings and gradually evolving protocol in the same setting longitudinally.

The hallmark of COVID-19 associated severe disease is increasing oxygen requirement and increasing C-reactive protein (CRP) levels, which is hypothesized to result from the cytokine storm syndrome (CSS).[3] This CSS probably acts by two ways: First, it leads to pneumonia and ultimately adult respiratory disease syndrome (ARDS) and second it leads to overreactive coagulation pathway, leading to microvascular thrombosis in the pulmonary vasculature. This dual brunt is the main reason for elevated morbidity and mortality.

At the start of the pandemic, Tocilizumab, an IL6 receptor antagonists had shown benefit in early case series.[4] But it was not available for most of our patients at our centre because of prohibitive cost ($600-1200 per patient). Pulse dose steroids were used to treat Haemophagocytic lymphohistocytosis (HLH) long before other IL6 antagonists were invented.[5] COVID19 associated CSS is strikingly similar to HLH in some aspects.[6] Keeping this scientific pathophysiological plausibility in mind, we decided to give high doses of steroids to patients of COVID19 ARDS. With the context of strong pathophysiological linking of potential steroid therapy amongst COVID19 patients and absence of any standardised treatment protocol at that time, motivated us to initiate steroid therapy amongst COVID19 ARDS patients. As this was a relatively naïve paradigm, standardisation of the dose could not be achieved despite of a qualitative consensus on steroid therapy.

Early administration of glucocorticoid in course of ARDS was associated with better survival in subgroup analysis of patients with SARS/MERS.[7] Recently published RECOVERY trial has shown positive effect of low dose glucocorticoids (6 mg dexamethasone OD for 10 days) on survival in treating COVID-19 ARDS patients on respiratory support.[8] But there has been no

consensus of usefulness of high dose steroids in literature in COVID19, since pulse steroids is theoretically associated with secondary infections.

We did retrospective chart analysis for patients admitted with COVID19 related ARDS in our ICU, to see whether steroids are associated with reduced mortality and whether it was associated with increased risk of infections.

Methods

Consecutive adults ≥18 years with nasopharyngeal swab PCR-confirmed SARS-CoV-2 infection with ARDS admitted (in ICU) in between 20th March,2020 to 15th July 2020 were included in chart review. This review was done in a single tertiary care teaching hospital in central India. The records were reviewed longitudinally from admission to outcome (either till death or discharge from hospital.

Definitions

We included only those patients who were given steroids in our ICU during the study period. All our patients in this analysis were being given varying doses of steroids. Time when patient had mMRC grade IV (breathlessness at rest) was noted according to patient history. The time difference between onset of severe breathlessness (mMRC grade IV) and first dose of steroid administration (as confirmed by the nursing chart) was counted. Dose and timing of steroid administration was decided by the consultant in-charge posted in ICU.

As we gained experience in management, we felt that high dose steroids (>500 Methylprednisolone) for 2-3 days followed by low dose (30-60 mg MPS) was better in management of patients with high oxygen requirement on admission (>10LPM). For patients with lower oxygen requirement than 10 LPM, low dose steroids (30-60 mg MPS) were sufficient to control cytokine storm. For comparative analysis, we grouped patients into two categories: Appropriate and Inappropriate.

We defined appropriate steroids as either:
   a) If FiO2 requirement to maintain spO2 >92% was more than 0.5 and he/she was given 500 mg of Methylprednisolone (MPS) or more as first dose of steroid within 24 hours of severe breathlessness. This group is henceforth

called as Early Pulse Steroids (EPS).

b) If FiO2 requirement to maintain spO2 >92% was less than 0.5 and he/she was given 30-60 mg of MPS or more as first dose of steroid within 24 hours of severe breathlessness. This group is henceforth called as Early Low Steroids (ELS).

Patients were defined in the inappropriate steroids group (or other group) if:

I. If first dose of MPS (in any dose) was started after 24 hours of severe breathlessness (late steroids).

Or

II. If patient's oxygen requirement (FiO2) was more than 0.5 to maintain spO2 >92% was and he/she was given less than 500 mg of MPS as first dose of steroids.

Disease severity was decided on the basis of P/F ratio on the day of admission. All patients admitted in our ICU had P/F < 300. For analysis purpose, we categorize these patients into two groups: P/F <150 (critically ill) and P/F in the range of 150-300 (mild to moderate ARDS). Requirement of NIV or invasive mechanical ventilation (IMV) or High Flow Nasal Canula (HFNC) was noted.

Process of data extraction- Data was extracted from the case records and treatment files of patients admitted in ICU. Data was retrieved by resident and consultant posted in ICU and was cross checked by another consultant. Data collection included timepoints like symptom onset, onset of shortness of breath, presumptive onset of severe breathlessness (mMRC grade IV), timing of steroid administration with respect to onset of severe breathlessness, date of hospitalization, date of outcome (discharge or death). Median value of SpO2 was taken for analysis for a 24-hour period. CRP, P/F ratio, FiO2 requirement and absolute lymphocyte counts were recorded and trend was analysed. Death was assessed during hospitalization and patients were followed until discharge from hospital. In our hospital, COVID19 ARDS patients are discharged only after negative RTPCR report.

All patients in our ICU had hypoxemia and were started on steroids along with empiric antibiotics (for gram negative coverage to prevent infections. Blood and endotracheal aspirate Culture Sensitivity were sent whenever patient had fever or TLC increased more than 14000/µl after steroid administration. Bacterial infection was diagnosed if patient had any of the culture reports positive. The retrospective chart analysis was cross checked by two senior consultants.

History of known comorbidities like Hypertension, Diabetes Mellitus (DM), Coronary Artery Disease (CAD), Chronic Kidney Disease(CKD), hypothyroidism was noted from history sheet.

Statistical Analysis

All statistical analysis was performed using statistical programming language R.[9] The data was prepared for analysis using standard data cleaning and data wrangling procedures using base R and the 'tidyverse' universe of packages. Exploratory analysis was done by cross-tabulations and bi-variate analysis. Data visualisation was done using grouped bar charts, box-plots and density ridgeline plots using functions from the 'ggplot2' package. A multivariate exact logistic regression was performed to estimate the conditional distribution of statistic for interest parameters namely steroid category and infection status conditional to the survival status of the patient. This Bayesian method uses the Markov Chain Monte Carlo(MCMC) method to derive the exact conditional inference for binomial data modelled by logistic regression. We used this method due to smaller sample size and presence of zero observations in a category formed by the outcome and categorical predictors. We used 'elrm'v1.2 package in R software which is available in open domain. All code and data necessary for reproducing the analyses and additional results are provided in the supplementary appendix.(Annexure-1)

Data was first transformed in a collapsed data set which consisted of the respected frequencies (trials; for 4 combinations of steroid and infection categories) and frequency of survival (success) in that combination. The Markov chain was created with 22000 iterations and 2000 burn in samples with final chain size as 20000. Three separate models were created with interest parameters as steroid category, infection category separately and in combination of both. In order to obtain the full conditional inference in the combination model we updated the length of the chain to 75000 (total iteration 80000 with 5000 burn-in

samples). The model diagnostic was estimated by trace plot and histogram to check convergence of the Markov chain. The presence of serial correlation which may confound the results was further investigated by Autocorrelation Function (ACF) plot.

Ethics issues- All admitted patients and their relatives are explained about disease condition , therapeutic options and prognosis routinely at our institute. This retrospective chart review study is part of study titled "Predictors of severity in COVID 19 infected patients: Observational Chart review". Institutional Human Ethics Committee (IHEC) approved the protocol vide LOP Number IHEC-LOP/2020/IM0281 , dated 15/07/2020.

Results
A total of 45 study participants were included in the study. The mean age of the population was 56.8 ± 15.9 years. The most baseline characteristics of the study population are provided in Table 1.

Table 1: Baseline characteristics of the study population

Characteristic	Group	Frequency (%)
Gender	Male	34 (75.6%)
	Female	11 (24.4%)
Age (in years)	Overall	56.8 ($\pm$ 15.9)*
	Male	56.7 ($\pm$ 16.1)*
	Female	57.2 ($\pm$ 15.9)*
	$\leq$60 years	26 (57.8%)
	>60 years	19 (42.2%)
Comorbidities	Diabetic	17 (37.8%)
	Hypertensive	20 (44.4%)
Steroid Given	Early High	22 (48.9%)
	Early Low	11 (24.4%)
	Late steroids	12 (26.7%)
ARDS Category	1	7 (15.6%)
	2	29 (64.4%)
	3	9 (20%)
Infection	Infected	12 (28.9%)
	Sterile	32 (71.1%)

Steroid Therapy	Appropriate	30 (66.7%)
	Inappropriate	15 (33.3%)
Outcome	Survived	26 (57.8%)
	Died	19 (42.2%)
Saturation at admission	Survived	80.88(14.51)**
	Died	73.73(14.42)**
P/F Ratio at Day1	Survived	130 (60.5)**
	Died	154.5(80.5)**
Lymphocytes count (/μL)	Survived	848(747) **
	Died	635 (393)**
Baseline CRP values (mg/L)	Survived	69.5 (23.27)**
	Died	154.5(120.25)**

* Mean (± SD)

**Median (IQR)- for some skewed variables

The results of the cross tabulation of outcome with the other variables are given in Table 2. It was found that age over 60 years and steroid therapy were found to be significant in preliminary bivariate analysis while gender, presence of comorbidity, category of ARDS and state of infection were found to be statistically non-significant.

Table 2: Cross-tabulation of basic characteristics with outcome of the study population

Characteristic	Group	Outcome		χ^2 statistic	p-value
		Survived	*Died*		
Age	≤60 years	21	5	11.204	0.000816
	>60 years	5	14		
Gender	Male	17	17	2.2681	0.1321
	Female	9	2		
Comorbidity	Present	10	8	0	1
	Absent	16	11		
ARDS Category	1	6	1	2.6933	0.2601
	2	15	14		
	3	5	4		
Steroid Category	Early High	15	7	7.2688	0.0264
	Early Low	8	3		

	Late steroids	3	9		
Infection	Infected	5	8	1.7935	0.1805
	Sterile	21	11		
Steroid Therapy	Appropriate	22	8	7.1166	0.007637
	Inappropriate/Other	4	11		

The relationship between severity (PFR status), infection status, age and diabetes status with assumed appropriate steroid dose and outcome is presented in a composite plot in Figure 1.

Figure 1. Composite plot of the distribution of steroid therapy and outcome. The x-axis represents the category of steroid therapy while the y-axis represents the number of study participants in each category. The colour of the bars represent the outcome of the study participants. A: Severity, B: Infection Category, C: Age D: Status of Diabetes

Figure 1 offers a visual evidence of effect of starting steroid early (<24 hours as per our definition of appropriateness) on the survival which is evident further in the presence of stratification with age, comorbidity, infections and extent of severity of disease.

Figure-2 Composite plot of timing and dose of steroid pulse therapy faceted by disease severity as measured in PFR .The x-axis represents the category of steroid therapy (which is subdivided into 3 subcategories) while the y-axis represents the number of study participants in each category. The colour of the bars represent the outcome of the study participants. Figure 2 is the extension of figure 1a where the survival status is further sub grouped by the three dose categories and stratified by the disease severity as measured by P/F ratio. The plot clearly indicate the benefit of early high dose (defined as >500/1000 mg early pulse steroid) in more severe disease(PFR<150).

In the next step the effect of early steroid on survival was quantified with choosing age >60 years and presence of infection as confounder. The Bayesian exact regression was performed to estimate the conditional distribution of the sufficient statistics of the parameter of interest (steroid category) on survival in the presence of nuisance parameter(adjusted by the effect of age and infection) . The equation the result of which is shown in table no.3.

Table No.3 - Exact logistic regression showing the regression parameter for steroid by maximizing the conditional likelihood function (Bayesian approach) :

Parameter of interest	Iterations	Burn-in	MC Size	Point estimates for regression parameter	95% CI for regression parameter (γ)		p-value
					Lower	Upper	
Steroid cat	50000	5000	45000	2.45	0.38	6.76	0.0054

This shows that regression parameter value is away from 0 (Ho: $\gamma=0$ and H1: : $\gamma \neq 0$)thus there seems to be an independent effect of appropriate dose of steroid after adjusting with age and infections. The trace plot was used to diagnosed whether the Markov chain was converged (Figure 3) which is not in this case, thus estimates seems robust methodologically.

Fig 3- Plot of the Markov chain produced by steroid category parameter.

Discussion

In this retrospective chart analysis study, we found that administration of early pulse dose steroids (>500 mg MPS) within 24 hours of start of severe breathlessness was associated with lower mortality in COVID19 ARDS (P/F <150). Also, we didn't find higher incidence of infections among those who

received high dose steroid and it was not associated with increased mortality due to secondary infections.

According to current understanding, COVID-19 infection timeline has probably following phases:

1. Initial phase of viral replication: Often there are only mild symptoms. Adaptive immunity is stimulated to respond to this replication. In this phase, only antivirals (HCQS or Remdesivir) are probably useful. If patient is not on oxygen support, steroids in early phase can be detrimental, as it can increase viral replication.[8]

2. Inflammatory phase: Some patients for currently unknown reasons enter hyperinflammatory phase. This usually starts between 8th to 12th day from initiation of symptoms. It is characterized by varying degree of hypoxemia and breathlessness. Roughly 5-10% of COVID19 patients develop CRS which is characterized by moderate to severe ARDS (PaO2/FiO2 <200) and elevated CRP/ferritin.[3] Immunosuppressive (steroids or tocilizumab) have been shown to reduce mortality in inflammatory phase.[4,8,10]

3. Resolution: Most patients with COVID19 do not have heightened immune response to viral replication and they usually do not have any significant symptoms.

Low dose steroid (Dexamethasone 6 mg OD or methylprednisolone 30 mg OD equivalent) administration during the early inflammatory phase (i.e. Phase 2) has been shown to be beneficial by blunting inflammatory cascade.[8] In RECOVERY trial benefit was shown in patients on respiratory support (either NIV/HFNC/Oxygen supplementation/ IMV). But in the preliminary report of RECOVERY trial, subgroup analysis on the basis of P/F ratio or oxygen requirement was not done. We found low dose steroids (40- 120 mg MPS) to be useful in patients with P/F >150, but patients with marked hyper-inflammation reaction (characterized by P/F <150 on ABG), early low-dose steroids if given were less effective to suppress Cytokine storm, as shown in Figure 2. High doses of steroids given early in the phase of hyperinflammation (within 24 hours) can potentially blunt the inflammation cascade if oxygen requirement is high.

In our analysis, steroids were found to be less successful in following conditions:

1. If first high dose of steroids was started after 24 hours of severe breathlessness (late steroids).

2. If low dose steroids were given in patients with initial P/F <150 even if given early (early low dose steroids)

Glucocorticoids have been widely used in other viral ARDS like influenza, Severe Acute Respiratory Syndrome (SARS), Middle East respiratory syndrome (MERS), and community-acquired pneumonia with varied success. Benefit of steroids was seen in SARS epidemic in a study done in china in 2005.[7] In subgroup analysis of 152 critical SARS cases, treatment with corticosteroid was associated with lower overall mortality, instant mortality, and shorter hospitalization stay (p < 0.05). In another study from Wuhan, China; 23 of fifty COVID19 ARDS patients in group receiving MPS (46.0%) died, while 21 of 34 (61.8%) died in group who did not receive MPS. The administration of methylprednisolone was associated with reduced risk of death in patients with ARDS (HR, 0.38; 95% CI, 0.20-0.72; $P = .003$)[11]

IMV was used as last resort in our ICU; patients were intubated only when patient failed NIV or HFNC. Only one of our patients put on IMV could be extubated till the data collection.

Timing of steroids is of utmost importance in patients of COVID19 ARDS. Similar findings were seen in a study from New York ,where usage of steroids within 48 hours was associated with better survival.[12] But in this series, only 7.1% patients who were given early steroids had sPO_2<90% on presentation. Also the steroids dose and P/F values were not mentioned in the brief report.

Currently, we use CRP and oxygen requirement guided steroid administration in our COVID ICU practice. When patients are in early inflammatory phase (characterised by elevated CRP) and oxygen requirement upto FiO2 0.5, these patients can be successfully managed with low dose steroids (60 -120 mg MPS OD for three days then 30 mg OD for 5-7 days), provided the first dose was given early. But in patients with FiO2 > 0.5, we believe steroids should be given

as early as possible in high doses (500 mg) for at least 2-3 days and then titrated according to CRP levels.

Often patients presents late in critical condition and reporting of RTPCR for COVID19 usually takes 24-36 hours in our hospital. So to avoid loss of precious time, we administer first dose of 500 mg MPS to the patient who has high pretest probability of COVID19 and oxygen requirement is high (>10 LPM). We administer second dose of MPS after confirming RTPCR report. We consider high pretest probability of patient being COVID19, if he/she fulfils all following criteria:

     i.   Clinical: history of SOB, fever and cough < 12 days

     ii.   Radiology: picture consistent with COVID19

               Or

        USG chest: bilateral B lines +/- consolidation

     iii.   TLC<12000 and Lymphocytes<1000

We have started giving first dose of MPS to our patients, if patient fulfills all three criteria and we have found to be highly useful in our ICU setting.

Our assessment of oxygenation shows that improvements in oxygenation starts after 24 hours of steroid administration. This was similar to trend seen after tocilizumab infusion seen in a case series, where P/F ratio remains stable for 1-2 days before increasing.[4] Methylprednisolone is a time tested, readily available, cost effective immunosuppressor unlike new immunosuppressor like tocilizumab, which is cost prohibitive and is available only in selected areas around world. Few RCT comparing steroids and Tocilizumab are underway and results are expected by end of 2020.[10] We used tocilizumab in only three patients due to prohibitive cost and lack of availability at our centre at the start of pandemic. It was used in two patients among appropriate steroid group (both survived) and one in late steroid group (she expired after a prolonged stay in hospital). All three patients were given high dose steroids plus tocilizumab and two of them developed superimposed fungal infections, gram positive and gram

negative bacteraemia. So both high dose steroids and tocilizumab should not be given in a single patient as it can lead to profound immunosuppression and worse outcome.

TLC rises in a significant proportion of patients, but there was no significant difference in rates of infections among EPS and OSG. Importantly, presence of infection had no significant effect on mortality.(Figure 1B) Although, there was no difference in mortality in these two groups, we had 9 patients had gram negative, 2 had gram positive bacteraemia and two had candidemia. One HIV positive patient also developed candidemia, but he was successfully weaned off ventilator. We strongly recommend performing standard of care hygiene precautions in COVID ICU, as these patients are already immunocompromised and superimposed infections can lead to poor outcome.

Another common side effect of high dose steroids is hyperglycaemia, Most of critically ill COVID19 patients are known diabetic, and these patient present with exceptionally raised sugar (sometimes in the range of 400-600 mg/dl) at presentation. Binding of coronavirus to ACE2 receptors found on pancreatic beta cells has been postulated as cause of significant hyperglycaemia.[13] Markedly raised sugar was present in significant proportion of our patients, but it was easily managed with insulin infusion in all the patients. And survival benefit of early high dose steroids was present even in diabetics.(Figure 1D) So we believe being diabetic should not be impediment for using steroids.

Limitations
Our study was a retrospective chart analysis from a single centre study with limited sample size. But we have taken the most critically ill patients and have used robust Bayesian Hypothesis. Secondly, some patients with known significantly high counts (TLC> 15000) at presentation were excluded from analysis, as these were not given steroids, so the findings should not be extrapolated to this subset of patients. Third, we did not analyse the time taken for RTPCR to become negative. Slower clearance of viral RNA was seen in patients with influenza, SARS and MERS who were treated with glucocorticoids. But significance of persistent positive RTPCR in terms of clinical outcome is unclear in patients who have improved clinically. [14]

In conclusion, high dose steroids if given early in the course of disease to COVID19 critically ill patients (P/F<150) can significantly reduce mortality. A well designed RCT to compare efficacy of low v/s high dose steroids in patients of moderate to severe COVID19 ARDS needs to be conducted to clarify the dose requirement.
