Abstract

Background: COVID-19 can course with respiratory and extrapulmonary disease. SARS-

CoV-2 RNA is detected in respiratory samples but also in blood, stool and urine. Severe

COVID-19 is characterised by a dysregulated host response to this virus. We studied

whether viral RNAemia or viral RNA load in plasma are associated to severe COVID-19

and also to this dysregulated response.

Methods: 250 patients with COVID-19 were recruited (50 outpatients, 100 hospitalised

ward patients, and 100 critically ill). Viral RNA detection and quantification in plasma was

performed using droplet digital PCR, targeting the N1 and N2 regions of the SARS-CoV-2

nucleoprotein gene. The association between SARS-CoV-2 RNAemia and viral RNA load

in plasma with severity was evaluated by multivariate logistic regression. Correlations

between viral RNA load and biomarkers evidencing dysregulation of host response were

evaluated by calculating the Spearman correlation coefficients.

Results: the frequency of viral RNAemia was higher in the critically ill patients (78%)

compared to ward patients (27%) and outpatients (2%) ($p<0.001$). Critical patients had

higher viral RNA loads in plasma than non-critically ill patients, with non survivors

showing the highest values. When outpatients and ward patients were compared, viral

RNAemia did not show significant associations in the multivariate analysis. In contrast,

when ward patients were compared with ICU patients, both viral RNAemia and viral RNA

load in plasma were associated with critical illness (OR [CI 95%], p): RNAemia (3.92

[1.183 - 12.968], 0.025), viral RNA load (N1) (1.962 [1.244 - 3.096], 0.004); viral RNA

load (N2) (2.229 [1.382 - 3.595], 0.001). Viral RNA load in plasma correlated with higher

levels of chemokines (CXCL10, CCL2), biomarkers indicative of a systemic inflammatory

response (IL-6, CRP, Ferritin), activation of NK cells (IL-15), endothelial dysfunction

(VCAM-1, angiopoietin-2, ICAM-1), coagulation activation (D-Dimer and INR), tissue

damage (LDH, GPT), neutrophil response (neutrophils counts, myeloperoxidase, GM-

CSF) and immunodepression (PD-L1, IL-10, lymphopenia and monocytopenia).

Conclusions: SARS-CoV-2 RNAemia and viral RNA load in plasma are associated to

critical illness in COVID-19. Viral RNA load in plasma correlates with key signatures of

dysregulated host responses, suggesting a major role of uncontrolled viral replication in the

pathogenesis of this disease.

Key words: SARS-CoV-2, cytokine, sepsis, COVID-19, plasma, RNAemia, viral RNA

load, ICU

Background

With well over 43 million cases and 1.56212 deaths globally, Coronavirus disease 2019

(COVID-19) has become the top economic and health priority worldwide [1]. Among

hospitalized patients, around 10–20% are admitted to the intensive care unit (ICU), 3–10%

require intubation and 2–5% die [2]. SARS-CoV-2 RNA is commonly detected in

nasopharyngeal swabs; however viral RNA can be found in sputum, lung samples,

peripheral blood, serum, stool samples, and to a limited extent urine [3] [4] [5] [6]. While

the lungs are most often affected, severe COVID-19 also induce inflammatory cell

infiltration, haemorrhage, and degeneration or necrosis in extra-pulmonary organs (spleen,

lymph nodes, kidney, liver, central nervous system) [7] [8]. Patients with severe COVID-

19 show signatures of dysregulated response to infection, with immunological alterations

involving moderate elevation of some cytokines and chemokines such as IL-6, IL-10 or

CXCL10, deep lymphopenia with neutrophilia, systemic inflammation (elevation of C

Reactive Protein, ferritin), endothelial dysfunction, coagulation hyper-activation (D-

dimers) and tissue damage (LDH) [9] [10] [11] [12] [13] [14].

Our hypothesis is that systemic distribution of the virus or viral components could be

associated to the severity of COVID-19, and, in turn to a number of parameters indicating

the presence of a dysregulated response to the infection.

While the SARS-CoV-2 virus has been reported to be difficult to culture from blood [4],

PCR based methods are able to detect and quantify the presence of genomic material of the

virus in serum or plasma, representing an useful approach to evaluate the impact of the

extrapulmonary dissemination of viral material on disease severity and also on the host

response to the infection [5] [15]. An excellent approach for achieving absolute

quantification of viral RNA load is droplet digital PCR (ddPCR). ddPCR is a next-

generation PCR method, which offers absolute quantification with no need of standard

curve and greater precision and reproducibility than currently available qRT-PCR methods,

as revised elsewhere [16].

We employed here ddPCR to detect and quantify viral RNA in plasma from COVID-19

patients discharged from the emergency room with mild severity, patients admitted to the

ward with moderate severity, and critically ill patients. Our objectives in this study were:

1) to evaluate if there is an association between SARS-CoV-2 RNAemia and viral RNA

load with moderate disease; 2) to evaluate if there is an association between SARS-CoV-2

RNAemia and viral RNA load with critical illness; 3) to evaluate the correlations between

SARS-CoV-2 RNA load in plasma and parameters of dysregulated host responses against

SARS-CoV-2.

Methods

Study design: 250 adult patients with a positive nasopharyngeal swab polymerase chain

reaction (PCR) test for SARS-CoV-2 performed at participating hospitals were recruited

during the first pandemic wave in Spain from March 16th to the 15th of April 2020. The

patients recruited were of three different categories. The first corresponded to patients

examined at an emergency room and discharged within the first 24 hours (outpatients

group, n=50). The second group were patients hospitalized to pneumology, infectious

diseases or internal medicine wards (wards group, n=100). Patients who required critical

care or died during hospitalization were excluded from this group, in order to have a group

of clear moderate severity. The third group corresponded to patients admitted to the ICU

(n=100). Patient`s recruited by participating hospital are detailed in the additional file 1.

20 healthy blood donors were included as controls. These controls were recruited during

the pandemics, in parallel to the SARS-CoV-2 infected patients, and were negative for

SARS-CoV-2 IgG. This study was registered at Clinicaltrials.gov with the identification

NCT04457505.

Blood samples: Plasma from blood collected in EDTA tubes samples was obtained from

the three groups of patients in the first 24 hours following admission to the emergency

room, to the ward, or to the ICU, at a median collection day since disease onset of 7, 8 and

10 respectively, and also. from 20 blood donors (10 men and 10 women).

Biomarker profiling: a panel of biomarkers was profiled by using the Ella-SimplePlex™

immunoassay (San Jose, California, U.S.A), informing of the following biological

functions potentially altered in severe COVID-19, based in the available evidence on

COVID-19 physiopathology [13] [17] and also in our previous experience on emerging

infections and sepsis [18] [19] [20] [21]: neutrophil degranulation: Lipocalin-2/NGAL,

myeloperoxidase; endothelial dysfunction: ICAM-1, VCAM-1/CD106, Angiopoietin 2; T

cell survival and function: IL-7, Granzyme B; immunosuppression: IL-1ra, B7-H1/PD-L1,

IL-10; chemotaxis: CXCL10/IP10, CCL2; Th1 response: Interleukin 1 beta, IFN-γ, IL-

12p70, IL-15, TNF-α, IL-2; Th2 response: IL-4, IL-10; Th17 response: IL-6, IL-17A;

granulocyte mobilization / activation: G-CSF, GM-CSF; coagulation activation: D-Dimer;

acute phase reactants: Ferritin (C Reactive protein and LDH were profiled in each

participant hospital by their central laboratories).

Detection and quantification of SARS-CoV-2 RNA in plasma: RNA was extracted from

100 µl of plasma using an automated system, eMAG® from bioMérieux® (Marcy l'Etoile,

France). Detection and quantification of SARS-CoV-2 RNA was performed in five µl of

the eluted solution using the Bio-Rad SARS-CoV-2 ddPCR kit according to

manufacturer's specifications on a QX-200 droplet digital PCR platform from the same

provider. This PCR targets the N1 and N2 regions of the viral nucleoprotein gene and also

the human ribonuclease (RNase) P gene using the primers and probes sets detailed in the

CDC 2019-Novel Coronavirus (2019-nCoV) Real-Time RT-PCR Diagnostic Panel [22].

Samples were considered positive for SARS-CoV-2 when N1 and/or N2 presented values

≥ 0.1 copies/µL in a given reaction. RNase P gene was considered positive when it

presented values ≥ 0.2 copies/µL, following manufacturer`s indications. The test was only

considered valid when RNase P gene was positive. Final results were given in copies of

cDNA / mL of plasma. IgG specific for the Nucleocapsid Protein of SARS–CoV-2 was

detected in 150 µl of plasma using the Abbott Architect SARS-CoV-2 IgG Assay (Illinois,

U.S.A). Viral RNA and SARS-CoV-2 IgG were profiled in the same plasma sample.

Statistical analysis: For the demographic and clinical characteristics of the patients, the

differences between groups were assessed using the Chi-square test / Fisher's Exact Test

where appropriated for categorical variables. Differences for continuous variables were

assessed by using the Kruskal-Wallis test with post hoc tests adjusting for multiple

comparisons. Multivariate logistic regression analysis was employed to evaluate the

association between viral RNAemia and viral RNA load in plasma with severity, in the

comparisons [outpatients vs ward patients] and [ward patients vs ICU patients]. Variables

showing significant differences between groups in each comparison in the Kruskal-Wallis

test were further introduced in the multivariate analysis as adjusting variables. The list of

variables considered as potential adjusting variables were [Age (years)], [Sex (male)],

[Alcoholism], [Smoker], [Drug abuse], [Cardiac disease], [Chronic vascular disease],

[COPD], [Asthma], [Obesity], [Hypertension], [Dyslipidemia], [Chronic renal disease],

[Chronic hepatic disease], [Neurological disease], [HIV], [Autoimmune disease], [Chronic

inflammatory bowel disease], [Type 1 diabetes], [Type 2 diabetes], [Cancer], [Invasive

mechanical ventilation], [Non-invasive mechanical ventilation], [SARS-CoV-2 IgG],

[Temperature (ºC)], [Systolic Pressure (mmHg)], [Oxygen saturation (%)], [Bilateral

pulmonary infiltrate], [Glucose (mg/dl)], [Creatinine (mg/dl)], [Na (mEq/L)], [K

(mEq/L)], [Platelets (cell x 10^3 / µl)], [INR], [D Dimer (pg/ml)], [LDH (UI/L)], [GPT

(UI/L)], [Ferritin (pg/ml)], [CRP (mg/dl)], [Haematocrit (%)], [Lymphocytes (cells/mm3)],

[Neutrophils (cells/mm3)], [Monocytes (cells/mm3)]. Multivariate logistic regression

analysis was performed using the "Enter" method, but also the backward stepwise

selection method (Likelihood Ratio) was employed in each case to confirm the association

between viral RNAemia and viral RNA load in plasma with disease severity ($p_{in} < 0.05$,

$p_{out} < 0.10$), not forcing entry of these variables in the model. Correlation analysis were

performed using the Spearman test applying the Bonferroni correction of the *p* value.

Variables evaluated for correlation with viral RNA load were: [Temperature (ºC)],

[Systolic Pressure (mmHg)], [Oxygen saturation (%)], [Lymphocytes (cells/mm3)],

[Neutrophils (cells/mm3)], [Monocytes (cells/mm3)], [Creatinine (mg/dl)], [LDH (UI/L)],

[GPT (UI/L)], [Platelets (cell x 10^3 / µl)], [INR], [CRP (mg/dl)], and all the biomarkers

analyzed by Ella- SimplePlex. Statistical analysis was performed with IBM SPSS® version

20 (IBM, Armonk, New York, USA).

Results

Clinical characteristics of the patients (Table 1): Patients requiring hospitalization

(either general ward or ICU) were older than those patients discharged to their home from

the ER. Critically ill patients were more frequently male than those in the other groups.

Comorbidities of obesity, hypertension, dyslipidemia and type 2 diabetes were more

commonly found in patients requiring hospitalization, with no significant differences found

in the comorbidities profile between critically ill and non-critically ill hospitalized patients.

14% of the patients in clinical wards required non-invasive mechanical ventilation, while

96% of the patients admitted to the ICU required invasive mechanical ventilation.

Critically ill patients had increased glucose levels, along with higher concentration of

neutrophils in blood, increased levels of ferritin and C-reactive protein (denoting activation

of the systemic inflammatory response). Increased levels of INR and D-dimers (reflecting

activation of the coagulation system), as well as LDH and GPT, which levels raise as

consequence of tissue and liver damage, were also observed in critically ill patients.

Patients admitted to the ICU also showed a lower haematocrit, pronounced lymphopenia

and lower monocyte counts at admission. ICU patients stayed longer in the hospital than

ward patients, with 49 % having a fatal outcome.

Viral RNAemia, viral RNA load in plasma and specific SARS-Cov-2 IgG in the three

groups of patients. As depicted in table 1, the frequency of the detection of SARS-CoV-2

viral RNA (RNAemia) was significantly higher in the critically ill patients (78%)

compared to ward patients (27%) and outpatients (2%) ($p<0.001$). Similarly, the group of

critically patients showed higher viral RNA loads in plasma than either ward or outpatients

($p<0.001$) (Table 1 and Figure 1). Non survivors showed the highest concentrations of viral

RNA in plasma: viral RNA load (N1 region) in ICU non survivors: 1587 copies / ml

[10248]; viral RNA load (N1 region) in ICU survivors 574 copies / mL [1872] (results

expressed as median [interquartile rank]); viral RNA load (N2 region) in ICU non

survivors: 2798 copies / ml [12012]; viral RNA load (N2 region) in ICU survivors 523

copies / mL [1478]. Patients admitted to the wards showed a significant higher frequency

of viral RNAemia than outpatients, but viral RNA loads were not significantly different

with the latter group (Table 1 and Figure 1). Critically ill patients also had a higher

frequency of specific SARS-CoV-2 IgG responses than the other groups (70% in ICU

compared to 52% and 49% in the outpatients and ward groups, $p < 0.05$, table 1). No

significant differences were found between the group of outpatients and those admitted to

the ward. The prevalence of viral RNAemia did not differ between those patients testing

positive and those testing negative for SARS-CoV-2 IgG (43.8 % and 40.4 % respectively,

$p =0.586$), who in addition showed no differences in viral RNA load (data not shown).

Patients with viral RNAemia showed no differences in the days since onset of symptoms

compared to those with no viral RNAemia (8.0 days [6.0]; 8.0 days [7.2], $p = 0.965$). In

contrast, samples from patients with SARS-CoV-2 IgG were collected later since disease

onset that those without SARS-CoV-2 IgG (10.0 days [7]; 7.0 days [6.0], $p = 0.003$)

Multivariate analysis to evaluate the association between viral RNAemia and viral

RNA load in plasma with moderate disease and critical illness. While the proportion of

patients with viral RNAemia was higher in the wards group compared to the outpatients'

group (table 1), the multivariate analysis did not show a significant association between the

presence of viral RNAemia and being hospitalised at the ward, with none of the both

methods employed (Additional files 2 and 3). In contrast, when the ward group was

compared with critically ill patients, a significant direct association was found between

viral RNAemia and viral RNA load in critically ill patients, using the "Enter" method

(Table 2) but also the backward stepwise selection method (additional file 4).

Correlations between viral RNA load in plasma and biological responses to SARS-

CoV-2 infection: viral RNA load in plasma (targeting either the N1 and the N2 regions)

showed the strongest direct correlations with plasma levels of CXCL10, LDH, IL-10, IL-6,

IL-15, myeloperoxidase and CCL-2 (MCP-1) and inverse correlations with lymphocytes,

monocytes and O2 saturation (Figure 2). These were the parameters whose levels varied

the most in critically patients compared with ward and outpatient groups (Figures 3 and 4

and additional file 5). CXCL10 was the most accurate identifier of viral RNAemia in

plasma (area under the curve (AUC), [CI95%], p) = 0.85 [0.80 – 0.89), <0.001), and IL-15

was the cytokine which most accurately differentiated clinical ward patients from ICU

patients (AUC: 0.82 [0.76 – 0.88], <0.001). Plasma viral RNA load also showed significant

direct correlations with levels of VCAM-1, PDL-1, GM-CSF, G-CSF, neutrophil counts,

IL-1ra, CRP, INR, D-dimer, TFNα, Angiopoietin-2, GPT, ICAM-1, IL-7 and Ferritin

(Figure 2), with most of these mediators showing the highest variations in the critically ill

patients (Figures 3 and 4 and additional file 5).

Discussion

Our study demonstrates that the presence of SARS-CoV-2-RNA in plasma is associated to

critical illness in COVID-19 patients, with the strength of association being the highest in

those patients with the highest viral RNA loads. This association was independent of other

factors also related to disease severity. Moreover, those critically ill patients who died

presented with higher viral RNA loads in plasma than those who survived. SARS-CoV-2

viral RNA was detected in the plasma of the vast majority of those COVID-19 patients

admitted to the ICU (78%). As far as we know, our study is the largest one to date using

ddPCR to quantify SARS-CoV-2 RNA load in plasma from COVID-19 patients, and the

only one with a multicentric design. Our results are in consonance with those from Veyer

et al, who, in a pilot study using this technology, found higher viral RNA loads and a

prevalence of RNA viremia of 88% in twenty six COVID-19 patients who were critically

ill [16]. The results are also in agreement with those of Hagman et al, who, using standard

RT-PCR technology, found that the presence of SARS-CoV-2 RNA in serum at hospital

admission was associated with a seven-fold increased risk of critical disease and an eight-

fold increased risk of death in a cohort of 167 patients hospitalised for COVID-19 [23].

Although our study did not determine if the presence of viral RNA in plasma reflects the

presence of live virus in peripheral blood, the association found between the presence and

concentration of viral RNA in plasma and critical illness suggests that viral replication is

more robust in severe COVID-19, and/or that critically ill patients with this disease are not

able to control viral replication. This notion is further supported by the correlations found

in our study between viral RNA load in plasma and hypercytokinemia involving CXCL10,

IL-10, CCL2, IL-6 and IL-15, where the levels of these cytokines were the highest in

patients with critical illness. The correlation between viral RNA load and higher levels of

cytokines has also been described in the severe infections caused by H5N1 and pandemic

H1N1 influenza strains [24] [25]. Active viral replication stimulates the secretion of

cytokines by the recognition of viral RNA by endosomal receptors such as toll like

receptor 7 (TLR7) in human plasmacytoid dendritic cells and B cells, or TLR8 in myeloid

cells [26]. While the elevation of CXCL10, IL-10, CCL2, IL-6 has been extensively

documented in severe COVID-19 [9] [10], our work demonstrates a clear correlation

between these cytokines and plasma viral load. Furthermore, we report for the first time a

major role of IL-15 in severe COVID-19. High levels of IL-15 in critically ill patients with

high SARS-CoV-2 RNA load in plasma could be an attempt to stimulate Natural Killer

cells to fight the virus [27]. We previously demonstrated that high levels of IL-15, along

with IL-6, constituted a signature of critical illness in H1N1 pandemic influenza infection

[20].

Viral RNA load correlated with higher levels of myeloperoxidase in plasma, which were

the highest in those patients admitted to the ICU. This is a marker of neutrophil

degranulation and a potent tissue damage factor which has been proposed to play a role in

the pathogenesis of ARDS secondary to influenza, by mediating claudin alteration on

endothelial tight junctions, eventually leading to protein leakage and viral spread [28]. In

this regard, the correlation found between viral RNA load in plasma and higher levels of

LDH and GPT could suggest a direct or indirect role of viral replication in mediating tissue

destruction in COVID-19.

Interesting, but less robust, direct correlations were found between viral RNA load in

plasma with GM-CSF and neutrophil counts in blood, further reinforcing the role of

neutrophil mediated responses in the pathogenesis of severe COVID-19. The direct

correlation with soluble PDL-1 is also relevant, since this the ligand of the inhibitory

co-receptor PD1 on T cells, which activation induces anergy of T lymphocytes [29]. This

finding reinforces the potential role of immune checkpoint inhibitors in severe COVID-19

[30]. In turn, the association found between viral RNA load in plasma and three mediators

of endothelial dysfunction (VCAM-1, angiopoietin 2 and ICAM-1), and with coagulation

activation markers (D-dimers and INR prolongation) suggests a potential virally linked

mechanism in the pathogenesis of endothelitis and thrombosis in COVID-19 disease [7].

Finally, the correlation with the acute phase reactants CRP and ferritin suggests a

connection between shedding of genomic material of the virus to the blood and the

induction of a systemic inflammatory response which is observed in those patients needing

critical care.

The strongest inverse correlations found in our study was between SARS-CoV-2 RNA

load in plasma and lymphocyte and monocyte counts in peripheral blood, for which

critically ill patients showed the lowest values. Active viral replication could be a

precipitating event in the pathogenesis of lymphopenia and monocytopenia in severe

COVID-19 patients [11] [31], by mediating direct cytopathic actions or stimulating the

migration of these cells to the extravascular space to reach the infected tissues [32].

A limitation of our work is its observational nature, which precludes to infer causality.

Nonetheless, the observed associations could serve as hypothesis generators, leading to the

development of animal models to confirm the potential link between SARS-CoV-2

replication and the dysregulated host responses observed in severe COVID-19.

Conclusion:

Presence of SARS-CoV-2 RNA in plasma is associated with critical illness in patients with

COVID-19. The strength of this association increases with viral RNA load in plasma,

which in turn correlates with key signatures of dysregulated host response in COVID-19

(figure 5). Our findings suggest a major role of uncontrolled viral replication in the

pathogenesis of this disease. Assessment of viral RNAemia and viral RNA load in plasma

could be useful to early detect those patients at risk of clinical deterioration, to assess

response to treatment and to predict disease outcome.

List of abbreviations

SARS-CoV-2: Severe acute Respiratory Syndrom-Coronavirus-2

LDH: Lactate dehydrogenase

G-CSF: Granulocyte colony-stimulating factor

TLR: toll like receptor

Declarations

Ethics approval and consent to participate: The study was approved by the Committee for Ethical Research of the coordinating institution, "Comite de Etica de la Investigacion con Medicamentos del Area de Salud de Salamanca", code PI 2020 03 452. Informed consent was obtained orally when clinically possible. In the remaining cases, the informed consent waiver was authorized by the Ethics committee.

Consent for publication: not applicable

Availability of data and materials: the datasets generated and/or analysed during the current study are not publicly available since they are still under elaboration for publication by the authors but are available from the corresponding author on reasonable request.

Funding

This work was supported by awards from the Canadian Institutes of Health Research, the Canadian 2019 Novel Coronavirus (COVID-19) Rapid Research Funding initiative (CIHR OV2 – 170357), Research Nova Scotia (DJK), Atlantic Genome/Genome Canada (DJK), Li-Ka Shing Foundation (DJK), Dalhousie Medical Research Foundation (DJK), the "Subvenciones de concesión directa para proyectos y programas de investigación del virus SARS-CoV2, causante del COVID-19", FONDO - COVID19, Instituto de Salud Carlos III (COV20/00110, CIBERES, 06/06/0028), (AT) and finally by the "Convocatoria extraordinaria y urgente de la Gerencia Regional de Salud de Castilla y León, para la financiación de proyectos de investigación en enfermedad COVID-19" (GRS COVID 53/A/20) (CA). DJK is a recipient of the Canada Research Chair in Translational

Vaccinology and Inflammation. APT was funded by the Sara Borrell Research Grant

CD018/0123 funded by Instituto de Salud Carlos III and co-financed by the European

Development Regional Fund (A Way to Achieve Europe programme). The funding sources

did not play any role neither in the design of the study and collection, not in the analysis, in

the interpretation of data or in writing the manuscript.

Authors 'contribution: JFBM, DJK, JB, RF, FB, AT and RM designed the study. JFBM

and DJK wrote the manuscript and interpreted the data. RA coordinated the clinical study

and drafted the figures. MGR, DM, PR, FPG, LT, RLI, EB, CA, JMG, JR, RM, MIF, GM,

MGE, DC, FDC, JFR, WT, PGJ, GR, IM, EG,IM, SP, SM, PGO, JAC, TRA, CP, JAB,

GR, RH, JB, PE, RC, JA, JGB, NM, NBL, LJV, BFC, MAM recruited the patients and /or

collected the clinical data. MDG, AO, RO, LMR and JME performed the assays for the

detection of SARS-CoV-2 IgG and viremia. APT, CD and AO developed the ddPCR

works; CD and NJ profiled the immunological mediators. SR, AMF and MMF developed

the statistical analysis and drafted the figures. AAK, ATO, AM and LF performed the

literature search. All authors read and approved the final manuscript.

Ackowledgements: we thank SEIMC-GESIDA Foundation for the scientific sponsoring of

this project. We thank also the "Biobanco del Centro de Hemoterapia y Hemodonación de

Castilla y León", which provided the plasma simples used in the healthy control group.

565 **Table 2: Multivariate logistic regression analysis comparing wards patients against**

566 **critically ill patients (Enter method).** The association between viral RNAemia or viral

567 RNA load targeting the N1 region, or viral RNA load targeting the N2 region with

568 critical illness was evaluated adjusting by major confounding factors.

Figure 1: Viral RNA load in plasma, targeting the N1 region (left) and the N2

region (right), in the three groups of patients. Results are provided as copies of

cDNA per mL of plasma.

Mediator	Correlation coefficients (p < 0.0012)		Biological implications
	VIRAL RNA LOAD (N1) (copies/mL)	VIRAL RNA LOAD (N2) (copies/mL)	
CXCL10			Chemotaxis of T cells
LDH (UI/L)			Tissue damage
IL-10 (pg/mL)			Immunosupression / immunomodulation
IL-6 (pg/mL)			Inflammation / Induction of Th17 adaptive immunity
IL-15 (pg/mL)			NK cell activation
Myeloperoxidase (pg/mL)			Neutrophil degranulation
CCL-2 (MCP-1) (pg/mL)			Chemotaxis of monocytes
VCAM-1 (pg/mL)			Endothelial dysfunction
PDL-1 (pg/mL)			Immunosupression / immunomodulation
GM-CSF (pg/mL)			Neutrophils and monocytes mobilization and activation
G-CSF (pg/mL)			Neutrophils mobilization and activation
Neutrophils (cells/mm3)			Innate immunity enhancement
IL-1ra (pg/mL)			Immunosupression / immunomodulation
CRP (mg/dl)			Inflammation (acute phase reactant)
INR			Coagulation activation
DDIMER (pg/mL)			Coagulation activation
TFNα (pg/mL)			Inflammation - induction of Th1 adaptive immunity
Angiopoietin-2			Endothelial dysfunction
GPT (UI/L)			Liver damage
ICAM-1 (pg/mL)			Endothelial dysfunction
IL-7 (pg/mL)			Lymphopoiesis and lymphocyte survival
Ferritin (pg/mL)			Inflammation (acute phase reactant)
Oxygen saturation (%)			Respiratory failure
Monocytes (cells/mm3)			Defective antigen presentation / phagocytosis
Lymphocytes (cells/mm3)			Adaptive immunity dysfunction

Color scale: -0.44 to 0.60

Figure 2. Heat map representing the Spearman correlation coefficients between viral RNA load in plasma targeting the N1 and the N2 regions and representative indicators of host dysregulated response.

Figure 3. Levels of laboratory parameters indicating host dysregulated response across groups. † indicates significant difference with the healthy control and the bars significant differences between the other groups.

606 **Figure 4: Levels of laboratory parameters indicating host dysregulated response**

607 **across groups.** † indicates significant difference with the healthy control and the bars

608 significant differences between the other groups.

Figure 5: Integrative model depicting the correlations found between the

indicators of host dysregulated responses and SARS-CoV-2 RNA load in plasma.
