## 22 **Abstract**

23 **Background:** In many countries in Sub-Saharan Africa, self-reported HIV testing history  
24 and awareness of HIV-positive status from household surveys are used to estimate the  
25 percentage of people living with HIV (PLHIV) who know their HIV status. Despite  
26 widespread use, there is limited empirical information on the sensitivity of those self-  
27 reports, which can be affected by non-disclosure.

28 **Methods:** Bayesian latent class models were used to estimate the sensitivity of self-  
29 reported HIV testing history and awareness of HIV-positive status in four *Population-*  
30 *based HIV Impact Assessment* surveys in Eswatini, Malawi, Tanzania, and Zambia.  
31 Antiretroviral (ARV) metabolites biomarkers were used to identify persons on treatment  
32 who did not accurately report their status. For those without ARV biomarkers, the  
33 pooled estimate of non-disclosure among untreated persons was 1.48 higher than those  
34 on treatment.

35 **Results:** Among PLHIV, the sensitivity of self-reported HIV testing history ranged 96%  
36 to 99% across surveys. Sensitivity of self-reported awareness of HIV status varied from  
37 91% to 97%. Non-disclosure was generally higher among men and those aged 15-24  
38 years. Adjustments for imperfect sensitivity did not substantially influence estimates of  
39 of PLHIV ever tested (difference <4%) but the proportion of PLHIV aware of their HIV-  
40 positive status was higher than the unadjusted proportion (difference <8%).

41 **Conclusions:** Self-reported HIV testing histories in four Eastern and Southern African  
42 countries are generally robust although adjustment for non-disclosure increases

43 estimated awareness of status. These findings can contribute to further refinements in  
44 methods for monitoring progress along the HIV testing and treatment cascade.

## 48 INTRODUCTION

49 Monitoring the HIV treatment and care cascade is central to the *Joint United Nations*  
50 *Programme on HIV/AIDS*' (UNAIDS) objective of ending the AIDS epidemic as a public  
51 health risk by 2030 (1). Routine tracking of population-level progress towards the  
52 UNAIDS' 2020 90-90-90 and 2030 95-95-95 diagnostic, treatment, and viral load  
53 suppression targets can guide public health initiatives and improve programmatic  
54 efficiencies (2). However, estimating progress towards the first pillar of the targets –the  
55 percentage of people living with HIV (PLHIV) who know their HIV status– is challenging.  
56 In sub-Saharan Africa (SSA), where 67% of the 38 million PLHIV were estimated to  
57 reside in 2019 (3), measures of awareness are typically constructed from data about  
58 self-reported HIV testing behaviour or reported directly from nationally representative  
59 household surveys (4-8).

60 Consideration of the potential for measurement bias is needed when interpreting self-  
61 reported survey data. Studies have shown that self-reporting about sensitive  
62 information, such as an individual's HIV testing history and HIV status, could be affected  
63 by non-disclosure (6, 9, 10). For example, inconsistencies have been documented in  
64 Kenya and Malawi between an individual's self-reported data and biomarkers for  
65 metabolites of antiretrovirals (ARVs) and viral load suppression (5, 10). While previous  
66 studies have sought to validate the accuracy of self-reported HIV status (10-12),  
67 analyzing recent data on both non-disclosure of self-reported HIV testing history and  
68 HIV status among PLHIV is key to improving the validity of these estimates.

69 Surveys that collect both self-reported information and ARV biomarkers can be used to  
70 assess the accuracy of self-reported HIV testing histories and HIV awareness status. In  
71 this study, Bayesian latent class models are used to estimate the sensitivity of self-  
72 reported HIV testing history and awareness of HIV status among PLHIV based on the  
73 presence of detectable ARVs (13).

## 74 **Methods**

### 75 **Study population**

76 The *Population-based HIV Impact Assessment* (PHIA) surveys are nationally  
77 representative multistage household-based surveys designed to provide population-  
78 level information on the burden of HIV disease and to document the progress of HIV  
79 programs (14-17). All four PHIA surveys with available microdata on PLHIV aged 15+  
80 years of age were included in our analysis: *Swaziland (Eswatini) HIV Incidence*  
81 *Measurement Survey 2* (2015-2016), *Malawi PHIA* (2015-2016), *Tanzania HIV Impact*  
82 *Survey* (2016-2017), and *Zambia PHIA* (2016).

### 83 **Self-reports and antiretroviral (ARV) status**

84 Participants who reported having ever received the results of any HIV test were  
85 classified as *ever tested and received results* (hereafter referred to as “*ever tested*”; see  
86 *Table S1*). Participants who reported having received a positive test result after any HIV  
87 test, were classified as *aware of HIV-positive status*. The specific laboratory algorithms  
88 used to detect ARVs varied across surveys, although all were analyzed in the same

89 laboratory, and included drugs in the nationally recommended first- and second- line  
90 regimens: efavirenz, lopinavir, and nevirapine (14-17).

## 91 **Bayesian latent class models**

92 Bayesian latent class models (18) were used to quantify the sensitivity of both self-  
93 reported HIV testing history and HIV status awareness among PLHIV. Cross-tabulations  
94 of self-reports with ARV biomarkers provide empirical information on their sensitivity  
95 among those with detectable ARVs (Figure 1A).

96 With regard to participants with detectable ARVs, we assumed that: (1) they had been  
97 tested for HIV, received their results, and were aware of their status; and (2) there were  
98 no false positives in the detection of ARV metabolites, self-reported HIV testing history,  
99 or awareness of HIV status.

100 As ARV metabolite data only provide information about the sensitivity of self-reports  
101 among participants on ARVs, the ratio of non-disclosure for PLHIV without detectable  
102 ARVs versus those with detectable ARVs was given a log-normal prior distribution with  
103 a mean of  $\log(1.48)$  (standard error: 4) to estimate the sensitivity of self-reports for  
104 people without detectable ARVs. This prior was elicited by reviewing available studies  
105 and meta-analyzing the evidence. The pooling of two studies conducted in rural  
106 Mozambique and Malawi (19, 20) suggests that people not receiving ARVs are 1.48  
107 more likely to not disclose their diagnosis. Additional analyses were conducted to  
108 investigate the influence of this prior on our results. Equations and prior distributions are  
109 presented in the *Supplementary Materials (Table S2 and Text S1)*.

110 Given known biases in self-reported estimates of HIV status awareness, analysts often  
111 manually reclassify individuals not aware of their status but with detectable ARVs –as in  
112 published PHIA reports. Most surveys, however, do not collect ARV biomarkers and  
113 only rely on self-reported information. To examine the impact of this partial adjustment,  
114 we compared the unadjusted, ARV-reclassified (as in PHIA reports), and Bayesian-  
115 adjusted estimates of PLHIV aware.

116 Models were run separately for each country and for subgroup analyses (i.e. age, sex,  
117 urban/rural and socio-economic status). Bayesian hierarchical models using Markov  
118 Chain Monte Carlo (MCMC), implemented through the JAGS software (21) and the  
119 *rjags* packages, were used to approximate the posterior densities (22, 23).

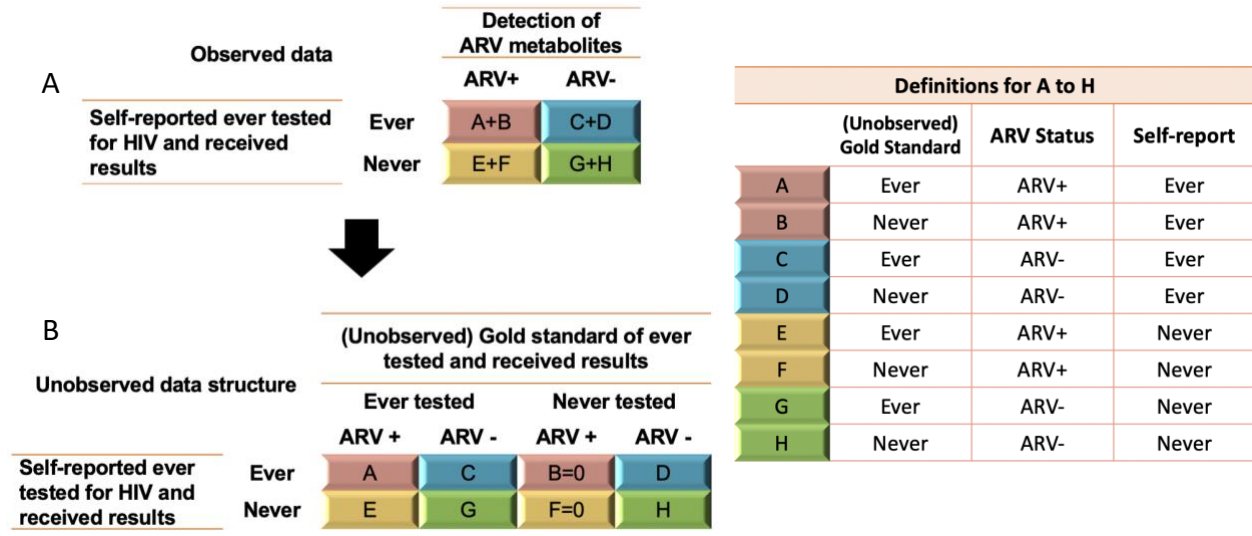

## 120 **Ethics**

121 Ethics approval for secondary data analyses was obtained from McGill University's  
122 Faculty of Medicine Institutional Review Board (A10-E72-17B).

123

124

125

126

127 **Figure 1.** Observed and unobserved data structure of self-reported *ever tested and*  
 128 *received results*, and antiretroviral (ARV) metabolites status. Definitions for cells A to H  
 129 are listed in the table. As it was assumed that participants with detectable ARV must  
 130 have been tested, cells B and F are *de facto* equal to zero. The same technique was  
 131 applied to the self-reported awareness of HIV status and was applied to all four Sub-  
 132 Saharan African countries.

133

## 134 **Results**

135 Overall, 3,003 PLHIV from Eswatini, 2,227 PLHIV from Malawi, 1,831 PLHIV from  
136 Tanzania, and 2,467 PLHIV from Zambia were included in the analyses. In all countries,  
137 a high fraction of PLHIV reported having ever been tested and the proportion of PLHIV  
138 reporting being aware of their status ranged from 68.0% in Tanzania to 86.5% in  
139 Eswatini. The proportion of PLHIV with detectable ARV metabolites was highest in  
140 Eswatini (76.0%), followed by Malawi (68.1%), Zambia (61.5%), and Tanzania (53.9%).

### 141 **Sensitivity of self-report**

#### 142 *Self-reported testing history*

143 Among participants with detectable ARVs, the estimated sensitivity was highest in  
144 Eswatini at 99.5% (95% credible interval [95%CrI]: 99.2-99.8%), followed by Malawi  
145 (98.2%; 97.5-98.8%), Zambia (97.4%; 96.5-98.1%), and Tanzania (96.6%; 95.3-97.6%)  
146 (Figure 2). For people without ARV metabolites, the estimated sensitivity was 2.4%  
147 points (0.1-11.4%) lower than those with detectable ARVs in Tanzania. The differences  
148 were smaller elsewhere. Detailed values can be found in *Supplementary Table 3*.

#### 149 *Self-reported awareness of HIV status*

150 The sensitivity of self-reported awareness of HIV-positive status among participants with  
151 ARV metabolites was 97.4% (96.7-98.0%) in Eswatini, 94.2% (93.0-95.4%) in Malawi,  
152 92.3% (90.5-93.8%) in Tanzania, and 91.6% (90.1-92.9%) in Zambia (Figure 2A). The  
153 estimated differences in sensitivity between PLHIV with ARV metabolites and those

154 without were 1.8% points (0.1-8.5%), 4.2% points (0.2-19.6%), 5.7% points (0.3-26.7%)  
155 and 6.2% points (0.3-29.0%) in Eswatini, Malawi, Tanzania, and Zambia respectively.

### 156 **Differences by gender, age, rural/urban, and socioeconomic status**

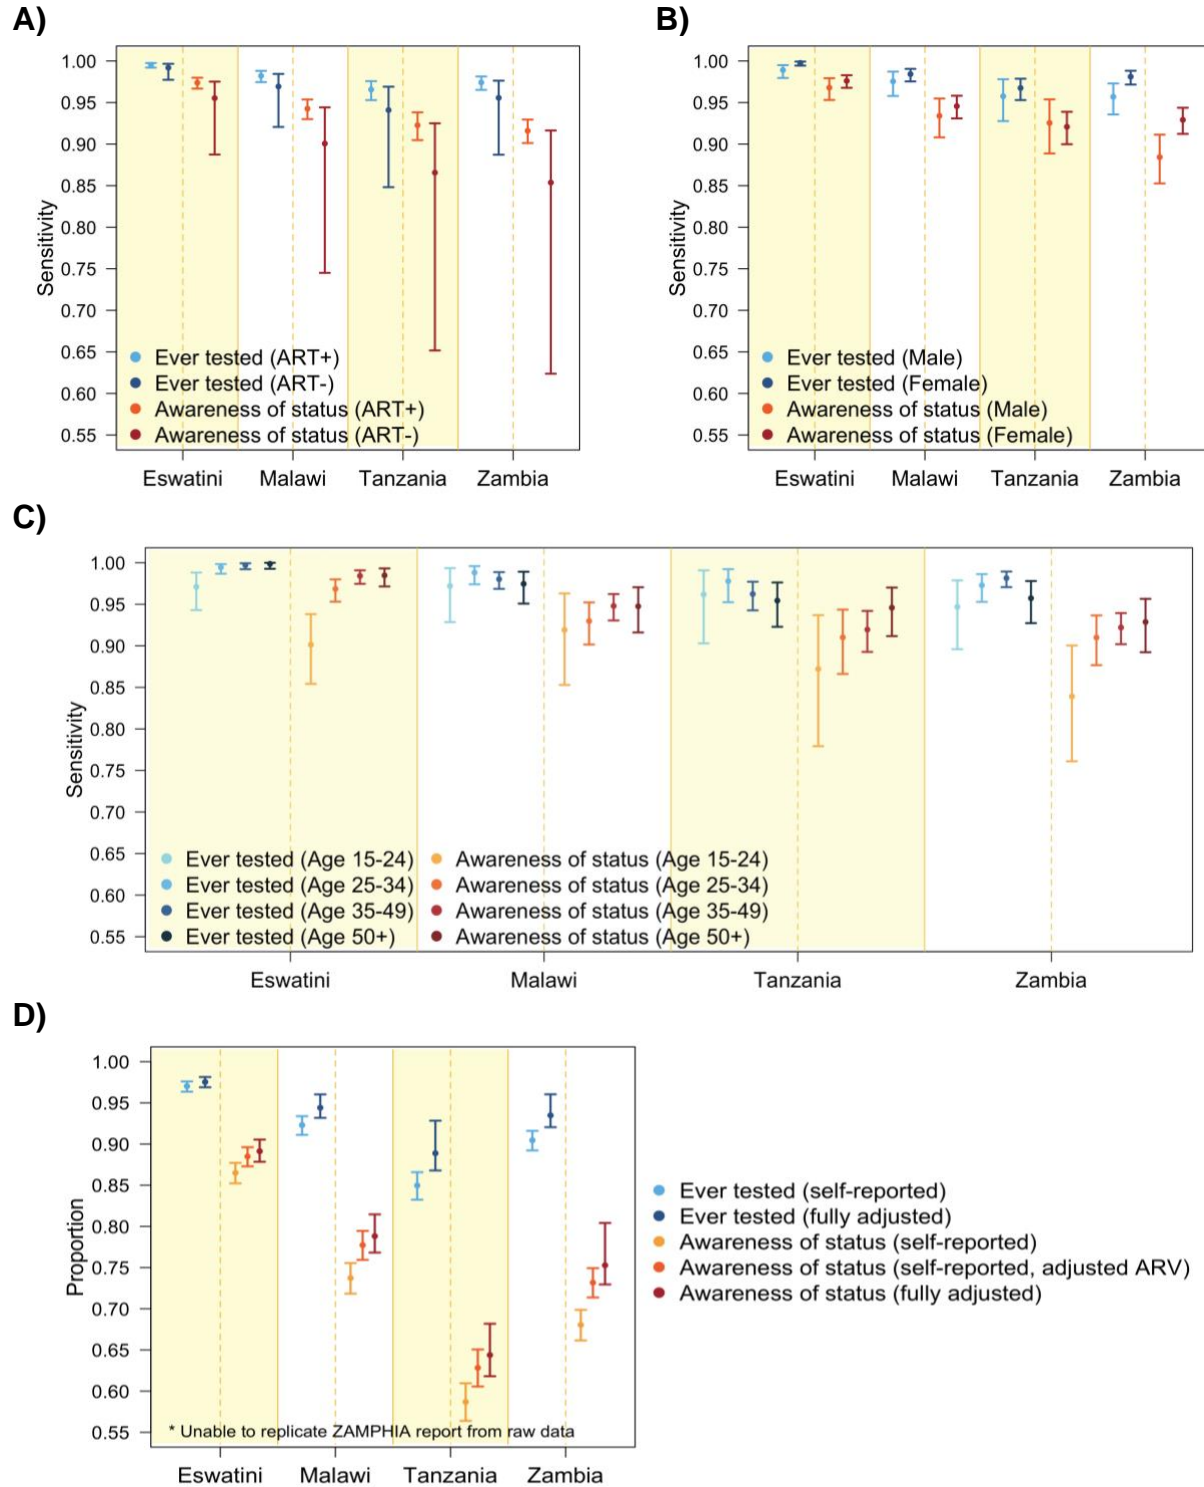

157 Among participants with detectable ARVs, women had 0.9-2.4% points higher  
158 sensitivities of self-reported HIV testing history and HIV status awareness than men  
159 (Figure 2B). The estimated sensitivities were the lowest at age 15-24 years (94.7-97.2%  
160 for HIV testing history and 83.9-91.9% for HIV status awareness) in all of the countries  
161 (Figure 2C). Participants residing in urban and rural areas had similar sensitivities  
162 (Figure S1A) and variations by socio-economic status (SES) were also small (Figure  
163 S1B and Figure S2).

### 164 **Adjusted proportion of PLHIV ever tested and PLHIV aware of their status**

165 Adjusting for imperfect sensitivity influenced the estimates of the self-reported  
166 proportion ever tested for HIV less (largest difference between the adjusted and the  
167 self-reports was 3.9% points in Tanzania) than the estimates of self-reported proportion  
168 of PLHIV aware of their status (largest difference was 7.2% points in Zambia) (Figure  
169 2D). Results were less affected by the assumed non-disclosure ratio for PLHIV without  
170 detectable ARV metabolites when antiretroviral therapy (ART) coverage is high (Figure  
171 S3).

**Figure 2.** Marginal posterior medians and 95% credible intervals for selected outcomes. Sensitivity of self-reported ever tested and received results, and awareness of HIV-positive status among people living with HIV (PLHIV) by: (A) antiretroviral (ARV) metabolites status, (B) gender (ARV+), and (C) age groups (ARV+). Panel D portrays the overall proportion of PLHIV ever tested who received results and the awareness of HIV-positive status (self-reported vs. adjusted ARV metabolites status vs. fully adjusted).

## 174 **Discussion**

175 Self-reported information on HIV testing and diagnosis are primary data sources used to  
176 monitor trends in the HIV treatment and care continuum (2, 9). These same data have  
177 also been proposed to estimate cross-sectional HIV incidence (24). In this study, we  
178 leveraged ARV biomarkers from four household representative surveys in Eswatini,  
179 Malawi, Tanzania and Zambia to estimate the sensitivity of self-reported HIV testing  
180 history and awareness of HIV status among PLHIV. We found that self-reports of HIV  
181 testing history have a high sensitivity (>96%) among PLHIV with detectable ARVs  
182 across these settings. Self-reported awareness of HIV status had a marginally lower  
183 sensitivity (>91%) in these same countries.

184 Subgroup analyses revealed nonnegligible lower sensitivities of both self-reported HIV  
185 testing history and awareness of status among male PLHIV and those aged 15-24 years  
186 which could result from social desirability bias (25). Additionally, differences in survey  
187 instruments could result in higher sensitivities for women. For example, in the PHIA  
188 survey, women are asked about HIV testing up to 4 times (before pregnancy, during  
189 pregnancy, during labor, and at their last HIV test), while men were asked only once. As  
190 women were classified based on the positive response to any of the 4 questions, this  
191 increased the probability of women disclosing their true status.

192 In this study, we estimated the sensitivity of the self-reports alone but when ARV  
193 biomarkers are available, presentation of cascade results from the surveys usually  
194 adjust these self-reports by reclassifying PLHIV that do not disclose their status but for  
195 which ARV metabolites are detected as “aware”. We have found that this partial

196 adjustment may be insufficient, especially if ART coverage is low in the surveyed  
197 population and the ratio of non-disclosure among those not on ART is high (26-29). To  
198 accurately estimate awareness of status, results must also be adjusted for non-  
199 disclosure among PLHIV with undetectable ARVs.

200 Our results need to be interpreted considering certain study limitations. First, only four  
201 PHIA surveys have publicly available micro-data, none of which are located in the West  
202 and Central African regions, where non-disclosure could be higher (30). The PHIA  
203 included here had some of the lowest levels of non-disclosure of these reviewed studies  
204 suggesting that other settings could have lower sensitivities. Second, our study design  
205 limited our assessment of the sensitivity of testing history to PLHIV, and findings should  
206 not be extrapolated to people not living with HIV. Third, it is not possible to empirically  
207 validate the sensitivity of self-reports among PLHIV without ARV metabolites. As such,  
208 we had to use information from two previous studies that used medical records to inform  
209 the non-disclosure ratio. Results could be sensitive to this non-disclosure ratio but the  
210 high ART coverage in the four countries mitigates this influence (*Figure S3*). Finally, the  
211 specificity of self-reports was assumed to be 100% which could lead to overestimating  
212 the proportion of PLHIV ever tested / aware of HIV-positive status. However, previous  
213 study has shown a high specificity of self-reported HIV testing results (11) implying that  
214 this assumption will likely have little impact on the outcomes.

215 Strengths of this study include the use of standardized survey and laboratory data (i.e.  
216 detection of ARV metabolites). Second, the Bayesian latent class models propagate  
217 uncertainty to our results by assuming prior distributions and generating posterior

218 credible intervals. Finally, we examined sex, age, urban/rural, and SES differences in  
219 the sensitivity of self-reports.

220 In conclusion, self-reported HIV testing histories have high sensitivities in the four  
221 countries examined but self-reported awareness of HIV status are lower. Whenever  
222 available, ARV biomarkers data can be used to adjust self-reports but such adjustments  
223 may still underestimate diagnosis coverage, especially if ART coverage is low in that  
224 population. Future research should extend this work in other regions and populations.
