28 **Abstract**

29 Therapeutic hypothermia following neonatal encephalopathy due to birth asphyxia reduces
30 death and cerebral palsy. However, school-age children without cerebral palsy treated with
31 therapeutic hypothermia for neonatal encephalopathy still have reduced performance on
32 cognitive and motor tests, attention difficulties, slower reaction times and reduced visuo-
33 spatial processing abilities compared to typically developing controls. We acquired diffusion-
34 weighted imaging data from school-age children without cerebral palsy treated with
35 therapeutic hypothermia for neonatal encephalopathy at birth, and a matched control group.
36 Voxelwise comparison of fractional anisotropy (33 cases, 36 controls) confirmed
37 microstructural alterations in widespread areas of white matter in cases, particularly in the
38 fornix, corpus callosum, anterior and posterior limbs of the internal capsule bilaterally and
39 cingulum bilaterally. In structural brain networks constructed using probabilistic tractography
40 (22 cases, 32 controls), graph-theoretic measures of strength, local and global efficiency,
41 clustering coefficient and characteristic path length were found to correlate with IQ in cases
42 but not controls. Network-based statistic analysis implicated brain regions involved in visuo-
43 spatial processing and attention, aligning with previous behavioural findings. These included
44 the precuneus, thalamus, left superior parietal gyrus and left inferior temporal gyrus. Our
45 findings demonstrate that, despite the manifest successes of therapeutic hypothermia, brain
46 development is impaired in these children.

48 connectivity; brain networks; diffusion-weighted imaging.

49

50 **1 Introduction**

51 Neonatal encephalopathy (NE), which often results from perinatal asphyxia, leads to a high
52 risk of death or disability, including cerebral palsy (CP) (Azzopardi et al., 2014; Marlow,
53 2005; O'Connor et al., 2017; Robertson et al., 1989). In the UK, approximately 2.6 per 1000
54 live births in 2015 were affected by NE secondary to perinatal asphyxia (Gale et al., 2018).
55 The recommended treatment for NE (National Institute for Clinical Excellence (NICE), 2010)
56 is therapeutic hypothermia (TH), which consists of reducing the infant's core temperature to
57 33.5°C for three days, commencing as soon as possible after the asphyxia (Azzopardi et al.,
58 2009; Rutherford et al., 2010). TH reduces the chance of death and disability at 18 months
59 (Jacobs et al., 2013), reduces likelihood and severity of CP (Jary et al., 2015) and increases
60 the incidence of survival with an IQ > 85 (Azzopardi et al., 2014). However, recent studies
61 have shown that children aged 6-8 years, who underwent TH at birth for NE and did not
62 develop CP, perform worse in motor and cognitive tests than controls (Jary et al., 2019; Lee-
63 Kelland et al., 2020) and have attention difficulties, slower reaction times and reduced visuo-
64 spatial processing abilities (Tonks et al., 2019). These motor deficits are not predicted by 18-
65 month developmental scores (Jary et al., 2019). Thus, despite the reduced occurrence of
66 severe disabilities following TH, aspects of brain development remain affected by NE.

67 Studies on children born with NE, prior to widespread use of TH (Gao et al., 2012; Ly et al.,
68 2015; Martinez-Biarge et al., 2012), and on animal models (Chakkarapani et al., 2010; Kyng
69 et al., 2015; Yue et al., 1997) indicate damage to white matter and subcortical structures,
70 caused by hypoxic-ischaemic brain injury. Some studies have shown an association between
71 hypothermia/rewarming and subcortical white matter apoptosis independent of hypoxic-
72 ischemic brain injury (O'Brien et al., 2019; Wang et al., 2016), whereas other findings
73 suggest no impact of hypothermia on the subcortical white matter (Gressens et al., 2008). It is
74 unknown how the interplay between the damage mechanisms of NE and the effects of TH
75 impact brain development.

76 Diffusion-weighted imaging (DWI) provides a non-invasive tool for investigating white
77 matter microstructure. Measurement of diffusion of water molecules through brain tissue
78 allows calculation of diffusion metrics such as fractional anisotropy (FA), which is related to
79 its microstructural properties. FA is affected by properties such as myelination and fibre
80 density (Le Bihan and Johansen-Berg, 2012) and has clinical relevance in patient cohorts
81 (Assaf and Pasternak, 2008; Dennis and Thompson, 2013a; Assaf *et al.*, 2019). We used

82 tract-based spatial statistics (TBSS) (Smith et al., 2006) to perform voxel-wise comparison of
83 FA across the brain's white matter, whilst controlling for multiple comparisons. We further
84 investigated white matter connectivity by constructing structural brain networks, or
85 connectomes (Sporns et al., 2005), in which nodes represent brain regions and edges were
86 determined by probabilistic tractography. We characterised structural networks by drawing
87 on techniques from graph theory (Bullmore and Sporns, 2009; Hagmann *et al.*, 2010a;
88 Fornito *et al.*, 2013; Bassett and Sporns, 2017), allowing comparison of quantitative
89 differences in whole-brain network structure. Such techniques have previously been used to
90 characterise the developing human connectome (Hagmann *et al.*, 2010b; Dennis and
91 Thompson, 2013b; Morgan *et al.*, 2018), as well as in the study of specific
92 neurodevelopmental complications such as CP (Arrigoni et al., 2016; Pannek et al., 2014) and
93 neurodevelopmental impairments following preterm birth (Brown et al., 2014; Muñoz-
94 Moreno et al., 2016). We then used the network-based statistic (NBS) (Zalesky et al., 2012,
95 2010) to look for subsets of connections (subnetworks) which were weakened in cases, and
96 subnetwork which related to measures of cognition.

97 Our findings demonstrate that, although TH reduces severe disabilities after NE, underlying
98 structural deficits are present which are associated with the cognitive differences found
99 between cases and controls at school-age. These differences are often overlooked as most
100 children given TH for NE do not demonstrate significant deficits in performance at 18
101 months.

102 **2 Materials and Methods**

103 **2.1 Participants**

104 Informed and written consent was obtained from the parents of participants, in accordance
105 with the Declaration of Helsinki. Ethical approval was obtained from the North Bristol
106 Research Ethics Committee and the Health Research Authority (REC ID: 15/SW/0148).

107 **2.1.1 Cases**

108 Eligibility criteria were as follows: gestation at birth ≥ 36 weeks and treatment with TH as
109 standard clinical care based on TOBY trial eligibility criteria including signs of perinatal
110 asphyxia and moderate to severe encephalopathy, confirmed by amplitude integrated
111 electroencephalogram (Azzopardi et al., 2009). Children were excluded if they had started
112 cooling later than six hours after birth, were cooled for less than three days, had received

113 Xenon as part of a neuroprotective feasibility study, had been found to have a metabolic or
114 genetic disorder, or if any major intracranial haemorrhage or structural brain abnormality
115 could be seen on the neonatal MRI scan. Cases were sequentially selected from the cohort of
116 children who received TH between 2008 and 2011. These data are maintained by the Bristol
117 Neonatal Neurosciences group at St Michael's Hospital, Bristol, UK, under previous ethics
118 approval (REC ID: 09/H0106/3). A diagnosis of CP was ruled out at 2 years and reconfirmed
119 at 6-8 years. Children were native English speakers and had no additional medical diagnosis
120 other than NE.

121 **2.1.2 Controls**

122 The control group consisted of children matched for age, sex and socio-economic status (Lee-
123 Kelland et al., 2020). Children were excluded if they were born before 36 weeks gestation,
124 had any history of NE or other medical issues of a neurological nature, or were not native
125 English speakers.

126 **2.2 Cognitive Assessment**

127 Cognitive performance was assessed using the Wechsler Intelligence Scale for Children 4th
128 Edition (WISC-IV) (Kaufman et al., 2006), which summarises raw score performance from
129 10 subsets into 10 scaled scores. These 10 scores are summed in four domains – verbal
130 comprehension, perceptual reasoning, processing speed and working memory – which are
131 combined to form a full-scale intelligence quotient (FSIQ) score. Cognitive testing was
132 administered by assessors who were not previously involved with the patients' care and were
133 blinded to case-control status.

134 **2.3 Image Acquisition**

135 T1-weighted images and DWI data were acquired with a Siemens 3 tesla Magnetom Skyra
136 MRI scanner at the Clinical Research and Imaging Centre (CRiCBristol), Bristol, UK. An
137 experienced radiographer placed children supine within the 32-channel receive only head-
138 coil, and head movement was minimised with memory-foam padding. Children wore
139 earplugs and were able to watch a film of their choice. A volumetric T1-weighted anatomical
140 scan was acquired for tissue segmentation and parcellation, with the magnetisation-prepared
141 rapid acquisition gradient echo (MPRAGE) sequence using the following parameters: echo
142 time (TE) = 2.19 ms; inversion time (TI) = 800 ms; repetition time (TR) = 1500 ms; flip
143 angle = 9°; field of view (FoV) 234 × 250 mm; 240 slices; 1.0 mm isotropic voxels. DWI data
144 were acquired for tractography and microstructural analysis, with a multiband echo-planar

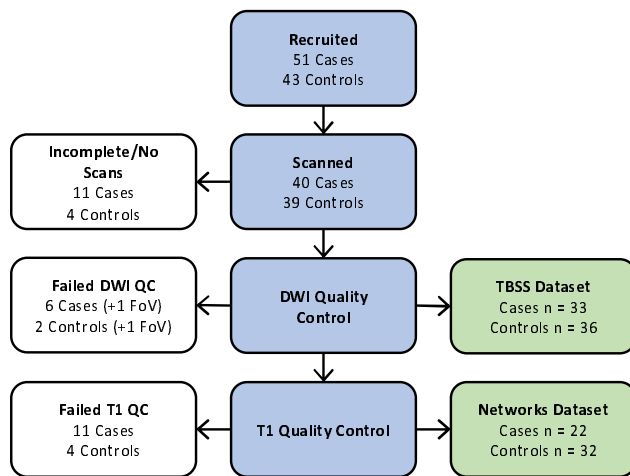

145 imaging (EPI) sequence, using the following parameters: TE = 70 ms; TR = 3150 ms; FoV
146 192×192 mm; 60 slices; 2.0 mm isotropic voxels, flip angle 90° , phase encoding in the
147 anterior-posterior direction, in-plane acceleration factor = 2 (GRAPPA (Griswold et al.,
148 2002)), through-plane multi-band factor = 2 (Moeller *et al.*, 2010; Setsompop *et al.*, 2012a,
149 b). For the purpose of data averaging and eddy-current distortion correction, two sets of
150 diffusion-weighted images were acquired with $b = 1,000$ s mm^{-2} in 60 diffusion directions,
151 equally distributed according to an electrostatic repulsion model, as well as 8 interspersed $b =$
152 0 images, with one data set acquired with positive phase encoding steps, then repeated with
153 negative steps (so-called, “blip-up, blip-down”), giving a total of 136 images.

154 **2.4 Quality Control**

155 The quality of the DWI data was assessed using the EddyQC tool (Bastiani et al., 2019) from
156 the FMRIB Software Library (FSL, <http://fsl.fmrib.ox.ac.uk>) (Smith et al., 2004). Scans were
157 rejected if the root-mean-square of all movement and eddy current metrics from EddyQC was
158 greater than one standard deviation above the mean for all participants.

159 T1-weighted anatomical images were assessed visually; any scans with severe movement
160 artefacts were rejected. The remaining scans were processed with the structural pipeline
161 described below, followed by further visual inspection of the parcellation and tissue
162 segmentation. Scans were further rejected at this stage if any moderate artefacts had caused
163 errors in the parcellation or segmentation.

164 Figure 1 shows the process of recruitment and scan quality control. We recruited 51 cases and
165 43 controls for this study. Of these, 7 cases and 4 controls did not want to undergo scanning.
166 A further 4 cases had incomplete data due to movement during the scan. DWI quality control
167 led to the rejection of a further 6 cases and 2 controls. One further case and one control were
168 rejected due to incorrect image volume placement. This left 33 case and 36 control scans
169 which passed the DWI quality control, which were used in the TBSS analysis. Of these
170 remaining 69 datasets, the anatomical scan for 11 cases and 4 controls was not of sufficient
171 quality to allow segmentation and parcellation, leaving 22 cases and 32 controls for network
172 analysis. Participant demographics are shown in Table 1.

173

174 **Figure 1: Recruitment.** Flowchart of participants at each stage of quality control. FoV =
 175 field of view, indicating the scans which were rejected due to incorrect image volume
 176 placement.

	TBSS			Network Analysis		
	Cases (n = 33)	Controls (n = 36)	p	Cases (n = 22)	Controls (n = 32)	p
Age	6.9 (6.0-7.9)	7.0 (6.1-7.9)	0.5555	7.0 (6.0-7.8)	7.0 (6.1-7.8)	0.5428
M/F	18/15	19/17	0.8894	12/10	16/16	0.7526
Socio-economic status	C1 (A-E)	B (A-D)	0.1568	C1 (A-D)	B (A-D)	0.0924
FSIQ	93 (62-115)	108 (75-137)	<0.0001	98 (62-114)	108 (75-137)	0.0010
Perceptual Reasoning	90 (67-123)	108 (84-145)	<0.0001	91 (67-110)	108 (84-145)	<0.0001
Processing Speed	97 (68-136)	106 (68-141)	0.0787	98.5 (75-136)	106 (68-141)	0.1221
Verbal Comprehension	98 (73-126)	109 (81-126)	0.0012	98 (73-126)	109 (81-126)	0.0114
Working Memory	97 (62-116)	105.5 (77-135)	0.0076	94 (62-116)	105.5 (77-135)	0.0290

177 **Table 1: Participant demographics.** Demographics are shown for each of the TBSS and
 178 network analysis groups. Median (range) is shown for age, socio-economic status and FSIQ.
 179 Socio-economic status is defined as follows: A = upper middle class, B = middle class, C1 =
 180 lower middle class, C2 = skilled working class, D = working class, E = casual worker or
 181 unemployed.

182 Anatomical images were visually assessed for focal lesions and abnormal signal intensities.
183 In the TBSS datasets, lesions were present in 1 case and 2 controls. In the network analysis
184 datasets, lesions were present in 1 control. These lesions were judged by the blinded assessor
185 (FC) to be non-severe, consequently these subjects were not excluded.

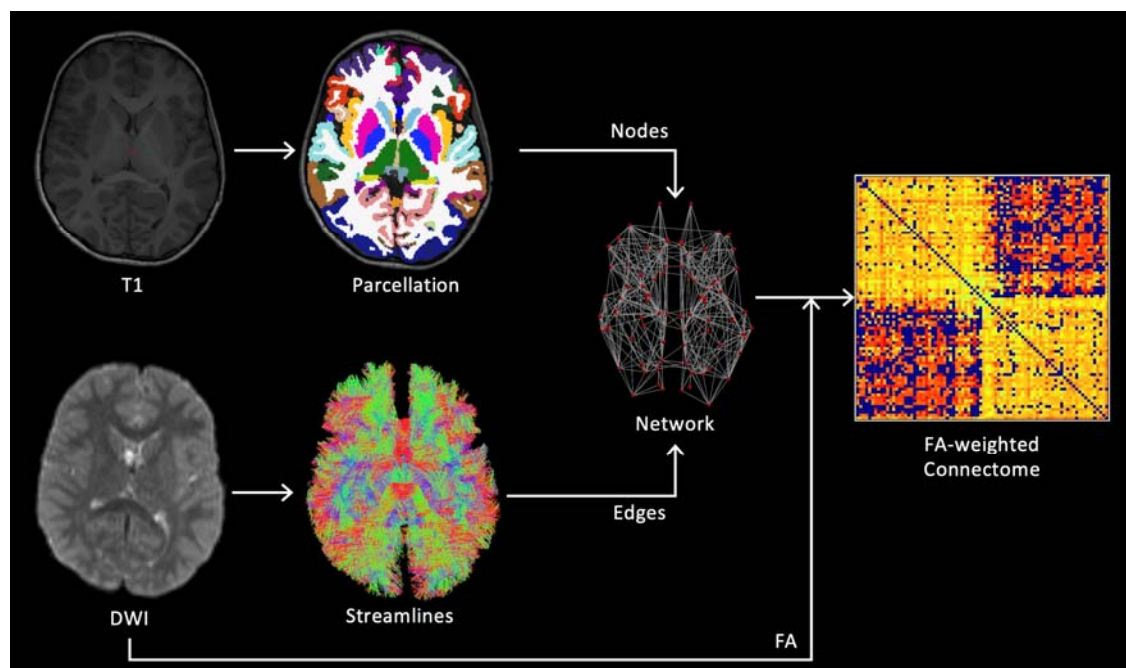

186 Note that previous findings from the same cohort demonstrate reduced performance in cases
187 in all WISC-IV domains (Lee-Kelland et al., 2020), whereas in the smaller group which
188 passed quality control in this study cases exhibit significantly reduced performance in
189 perceptual reasoning, verbal comprehension, working memory and FSIQ. Though processing
190 speed was reduced in cases in this study, the difference was not significant (see Table 1).

191 **2.5 TBSS**

192 Voxelwise statistical analysis of the FA data was carried out using TBSS (Smith et al., 2006),
193 part of FSL. FA images were generated by fitting a tensor model to the diffusion data using
194 FSL's FDT software. All images were then nonlinearly registered to one subject, chosen
195 automatically by finding the most representative subject, which was then affine registered to
196 MNI152 standard space. This is the recommended procedure when testing data from children,
197 which may not register well to an adult template (Smith et al., 2006). The mean FA image
198 was then eroded to create a skeletonised representation of the white matter tracts. Each
199 subject's registered FA image was then projected onto this skeleton to allow voxelwise
200 statistics.

201 **2.6 Structural Network Construction**

202 A weighted connectome was constructed for each subject, with nodes defined by parcellation
203 of the anatomical scan and edges determined by probabilistic tractography using the DWI
204 data. The processing pipeline, described in more detail below, is summarised in Figure 2.

205

206 **Figure 2: Processing pipeline.** Method for constructing structural brain networks from T1
207 and DWI data. Cortical and sub-cortical nodes were defined by segmentation of the T1-
208 weighted structural scan. Edges were determined by seeding streamlines from the cortical
209 grey/white matter interface and performing tractography using the fibre orientation
210 distribution obtained by spherical deconvolution of the measured diffusion signal. Edges
211 were weighted by the mean FA along all streamlines passing between the corresponding pair
212 of nodes, and the resulting network was represented by a connectivity matrix.

213 2.6.1 Node Definition

214 T1-weighted anatomical images were denoised with the Advanced Normalization Tools
215 DenoiseImage tool (<http://github.com/ANTsX/ANTs>) (Manjón et al., 2010). Brain extraction
216 was performed with either SPM8-VBM (<http://fil.ion.ucl.ac.uk/spm>) (Ashburner and Friston,
217 2005) or CAT12 (<http://www.neuro.uni-jena.de/cat>) (Gaser and Dahnke, 2016) depending on
218 which gave better delineation of the brain surface for each subject. Each subject's T1-
219 weighted image was parcellated, using FreeSurfer (<http://surfer.nmr.mgh.harvard.edu>)
220 (Fischl, 2012), according to the Desikan-Killiany atlas (Desikan et al., 2006) (a total of 84
221 regions; 34 cortical, 7 subcortical and 1 cerebellar per hemisphere). The FIRST (Patenaude et
222 al., 2011) subcortical segmentation tool from FSL was found to give better segmentation of
223 subcortical structures (including the hippocampus and amygdala) than FreeSurfer, so this was

224 combined with the cortical parcellation from FreeSurfer using the labelsgmfix tool from
225 MRtrix (www.mrtrix.org) (Tournier et al., 2019).

226 **2.6.2 Edge Definition**

227 DWI data were corrected for eddy current induced distortions and subject movements using
228 EDDY (Andersson and Sotiropoulos, 2016) and TOPUP (Andersson et al., 2003), from FSL.
229 Subsequent DWI processing and tractography steps were performed using MRtrix. The
230 response function (the DWI signal for a typical fibre population) was estimated from the data
231 (Tournier et al., 2013) in order to calculate the fibre orientation distribution (FOD) by
232 performing constrained-spherical deconvolution of the response function from the measured
233 DWI signal (Tournier et al., 2007). The normalised FOD image and the five-tissue-type
234 segmentation of the T1-weighted anatomical image were used to perform anatomically-
235 constrained tractography (Smith et al., 2012) using second-order integration over FODs
236 (Tournier et al., 2010), with the following parameters: step size = 1 mm, minimum length =
237 50 mm, cutoff FOD magnitude = 0.1, maximum angle between steps = 30°. Streamlines were
238 seeded in the interface between grey and white matter and only accepted if they terminated in
239 subcortical or cortical grey matter. Terminated streamlines which were not accepted were
240 allowed to backtrack to a valid point to be resampled (Smith et al., 2012). This method was
241 used to generate 10 million streamlines which were subsequently filtered to 1 million using
242 spherical-convolution informed filtering of tractograms (Smith et al., 2013) in order to
243 improve biological plausibility and remove length bias. FA images were then used to assign a
244 weight to each streamline according to the mean FA along its path. In order to construct a
245 weighted graph for each subject, edges were defined between any pair of nodes connected by
246 at least one streamline, with the connection strength defined by the mean FA along all
247 streamlines connecting the nodes.

248 **2.7 Network Metrics**

249 We selected the following metrics to quantify properties of the FA-weighted structural
250 connectivity networks: average strength, characteristic path length, global efficiency, local
251 efficiency, clustering coefficient, modularity and small-worldness. These are defined below
252 (for an in-depth description see Rubinov and Sporns, 2010).

253 The strength of a node is defined as the sum of the weights of all edges connected to the
254 node. The average weight for the entire graph is equal to the average node strength across all
255 nodes. The characteristic path length of the graph is the average of the shortest path from

256 each node to every other node, where the edge distances used to calculate path lengths are
257 defined inversely to edge weights (making stronger connections equivalent to shorter paths).
258 Note that this does not reflect physical distance between regions in the brain. A shorter
259 characteristic path length indicates stronger connectivity across brain regions, thus implying
260 stronger potential for integration (Rubinov and Sporns, 2010). Global efficiency is the
261 average of the inverse of the shortest path length. This has a roughly inverse relationship with
262 characteristic path length, and therefore indicates integration (Bullmore and Sporns, 2009).
263 However, the two metrics differ in the edges they are influenced by; the calculation of
264 characteristic path length is more dependent on longer paths, whereas global efficiency is
265 more dependent on shorter paths.

266 Local efficiency of a given node is the average of the inverse of the shortest path length
267 between the immediate neighbours of that node. This is then averaged across all nodes to give
268 a single measure for the whole graph. The clustering coefficient gives the number of
269 connections between the nearest neighbours of a node as a fraction of the maximum number
270 of possible connections. Modularity indicates how well the network can be split up into
271 relatively separate communities (i.e. modules) of nodes by measuring a normalised ratio of
272 the number of within-module connections to the number of between-module connections.
273 Local efficiency, clustering coefficient and modularity indicate the efficiency of local
274 information transfer, thus indicating the potential for segregated functional processing
275 (Bullmore and Sporns, 2009; Rubinov and Sporns, 2010).

276 Both integration and segregation are required for brain networks to carry out localised and
277 distributed processing simultaneously (Tononi et al., 1994). The degree to which a network
278 exhibits both segregation and integration is measured by the small-worldness of the network
279 (Muldoon et al., 2016; Rubinov and Sporns, 2010). A high degree of small-worldness is
280 characterised by a high clustering coefficient and low characteristic path length compared to
281 random graphs. We measured small-worldness with small-world propensity (Muldoon et al.,
282 2016). All other metrics were calculated with the Brain Connectivity Toolbox
283 (<http://www.brain-connectivity-toolbox.net>) (Rubinov and Sporns, 2010).

284 **2.8 Statistical Analysis**

285 Group differences between case and control network metrics were tested using two-tailed,
286 unpaired t-tests. Correlation of network metrics with cognitive score was then tested by
287 calculating the partial Pearson correlation coefficient, including age and sex as covariates. In

288 order to reduce the effect of multiple comparisons and increase statistical power, each
289 network metric was tested for correlation with FSIQ, not with every WISC-IV domain.
290 Bonferroni correction was applied to correct for multiple comparisons. Statistical analysis of
291 the network metrics was performed in MATLAB (R2018b, Mathworks). For TBSS,
292 significance was tested using FSL's non-parametric permutation testing software,
293 RANDOMISE (Winkler et al., 2014). We used 10,000 permutations and applied threshold-
294 free cluster enhancement to correct for multiple comparisons. Significant results have
295 corrected $p < 0.05$.

296 **2.8.1 Network-Based Statistic (NBS)**

297 We used NBS to test the hypothesis that cases exhibit reduced connectivity (i.e. reduced FA)
298 compared to controls, based on previously reported findings of reduced FA in white matter in
299 neonates treated with TH for NE (Lally et al., 2019; Tusor et al., 2012). We also explored
300 group differences in the relationship between cognitive scores and connectivity.

301 NBS (Zalesky et al., 2012, 2010) is a nonparametric, permutation-based approach for
302 controlling family-wise error rate (FWER) on the level of subnetworks. NBS identifies
303 connected subnetworks in which each edge satisfies the given contrast (e.g. group differences
304 in connectivity). The t-statistic is calculated for each edge in the network, then thresholded at
305 a chosen value. Of the remaining suprathreshold edges, the size of each connected
306 subnetwork (given by the number of edges) is stored. This process is repeated for random
307 permutations of the data to estimate the null distribution. The FWER-corrected p-value for
308 each subnetwork is given by the number of permutations for which the largest connected
309 subnetwork in the permuted data is the same size or larger than the given subnetwork,
310 normalised by the number of permutations.

311 We tested for reduced connectivity in cases compared to controls (one-tailed) and for group
312 differences in the dependence of cognitive scores on edge weights (two-tailed). We tested all
313 four cognitive domains for correlation (perceptual reasoning, processing speed, verbal
314 comprehension, working memory) in addition to FSIQ. We used 10,000 permutations to
315 calculate the p-value. In order to only test robust edges, only connections present in >50% of
316 cases and >50% of controls were assessed. Age and sex were included as covariates in a
317 general linear model in all tests (design matrices are shown in Supplementary Tables 2 and
318 3). As recommended in the literature (Zalesky et al., 2012, 2010), a range of t-statistic
319 thresholds were tested (2.5-3.5) to find the value which gave robust results (Supplementary

320 Figure 2). This procedure allows identification of large subnetworks with subtle effects (at
321 low primary thresholds) as well as smaller subnetworks with strong effects (at high primary
322 thresholds). Significant results have $p < 0.05$ (FWER-corrected).

323 **2.9 Visualisation**

324 Subnetworks were visualised with the BrainNet Viewer (<https://www.nitrc.org/projects/bnv/>)
325 (Xia et al., 2013) and as Circos connectograms (<http://www.circos.ca>) (Krzywinski et al.,
326 2009).

327 **2.10 Data Availability**

328 The data that support the findings in this article are available upon reasonable request to the
329 corresponding author.

330 **3 Results**

331 **3.1 TBSS**

332 Figure 3 shows the results of voxelwise comparison of FA using TBSS, demonstrating
333 widespread reduction in FA in cases compared to controls. The effect is most prominent in
334 the fornix, the corpus callosum, anterior and posterior limbs of the internal capsule
335 bilaterally, and the cingulum bilaterally, but can also be seen in other distributed areas of
336 white matter. These results demonstrate extensive alterations to white matter microstructure
337 in cases. This analysis was repeated with age and sex included as covariates in a general
338 linear model; the results were largely unchanged (see Supplementary Figure 1).

339

340 **Figure 3: TBSS results.** Results of voxelwise comparison of FA on the white matter
341 skeleton (green). Significant results are indicated by the colour bar ($p < 0.05$, TFCE
342 corrected). These are overlaid on the MNI standard template. Labels indicate some major
343 white matter tracts and regions. Abbreviations are as follows: anterior thalamic radiation
344 (ATR), corpus callosum (CC), external capsule (EC), internal capsule (IC), inferior fronto-
345 occipital fasciculus (IFOF), inferior longitudinal fasciculus (ILF), superior longitudinal
346 fasciculus (SLF), uncinate fasciculus (UF). Differences are most notable in the IC, CC, fornix
347 and cingulum.

348 **3.2 Network Metrics**

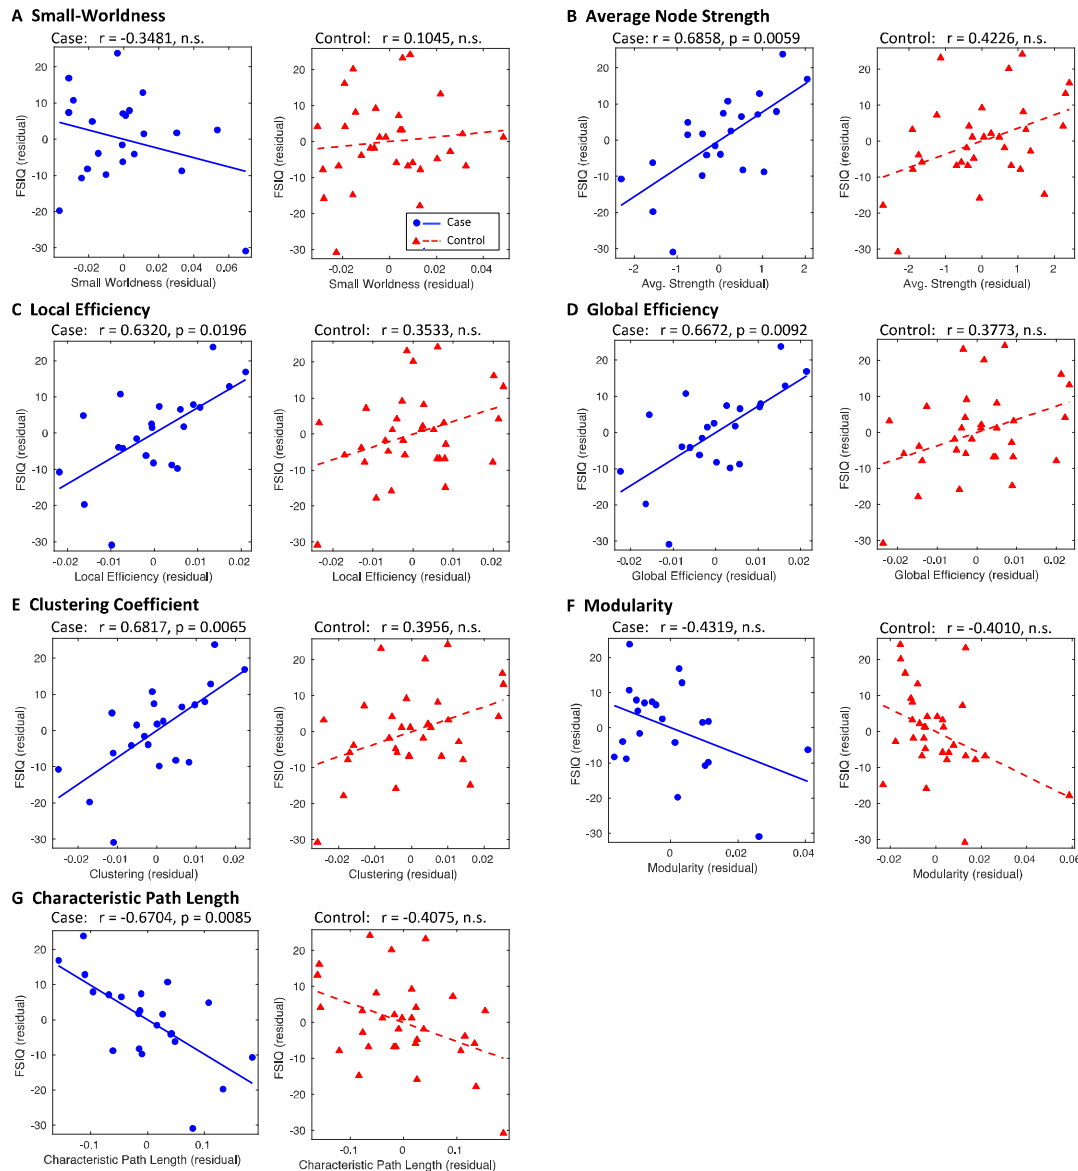

349 **3.2.1 Group Differences**

350 No significant group differences were found in network metrics (see Supplementary Table 1).
351 Notably, small-world characteristics were expressed robustly across the entire cohort with all
352 subjects expressing a small-world propensity greater than 0.82 (networks with small-world
353 propensity > 0.6 are considered small-world (Muldoon et al., 2016)).

354 **3.2.2 Cognitive Correlations**

355 Figure 4 shows the correlation of network metrics with FSIQ. In cases, FSIQ was
356 significantly correlated with average node strength ($r = 0.6858$, $p = 0.0059$), local efficiency
357 ($r = 0.6320$, $p = 0.0196$), global efficiency ($r = 0.6672$, $p = 0.0092$), clustering coefficient ($r =$

358 0.6817, $p = 0.0065$) and characteristic path length ($r = -0.6704$, $p = 0.0085$). In controls,
 359 network metrics exhibited the same general trends as in cases, however none of the
 360 correlations were significant, despite there being a comparable spread in the residuals.

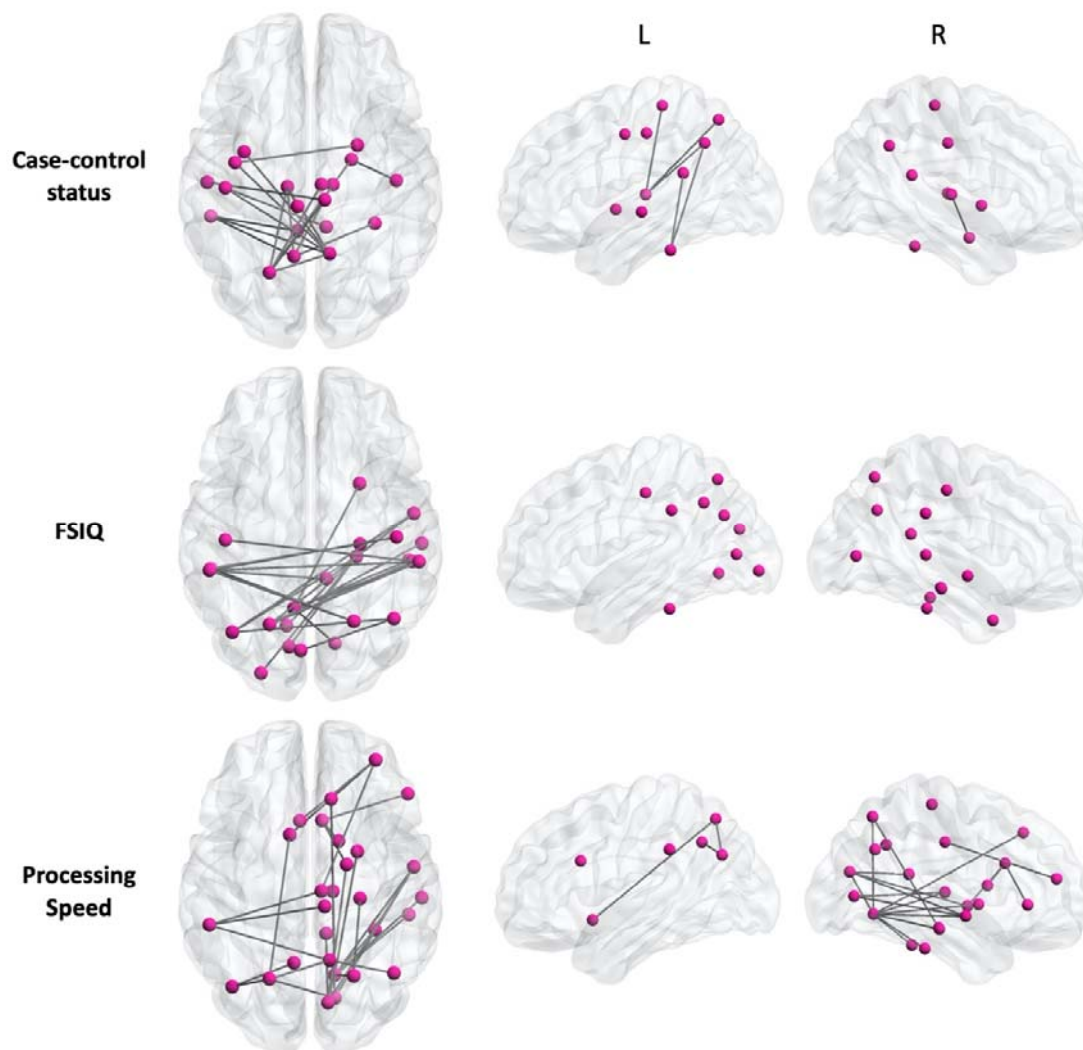

361

362 **Figure 4: Correlation of network metrics with FSIQ.** Network metrics and FSIQ were
 363 controlled for age and sex, with residuals plotted for cases (blue circles) and controls (red
 364 triangles). These are fitted with a blue solid line and red dashed line for cases and controls
 365 respectively. Where $p > 0.05$, plots are labelled as not significant (n.s.). p-values are
 366 Bonferroni corrected for the number of correlations performed.

367 **3.3 NBS**

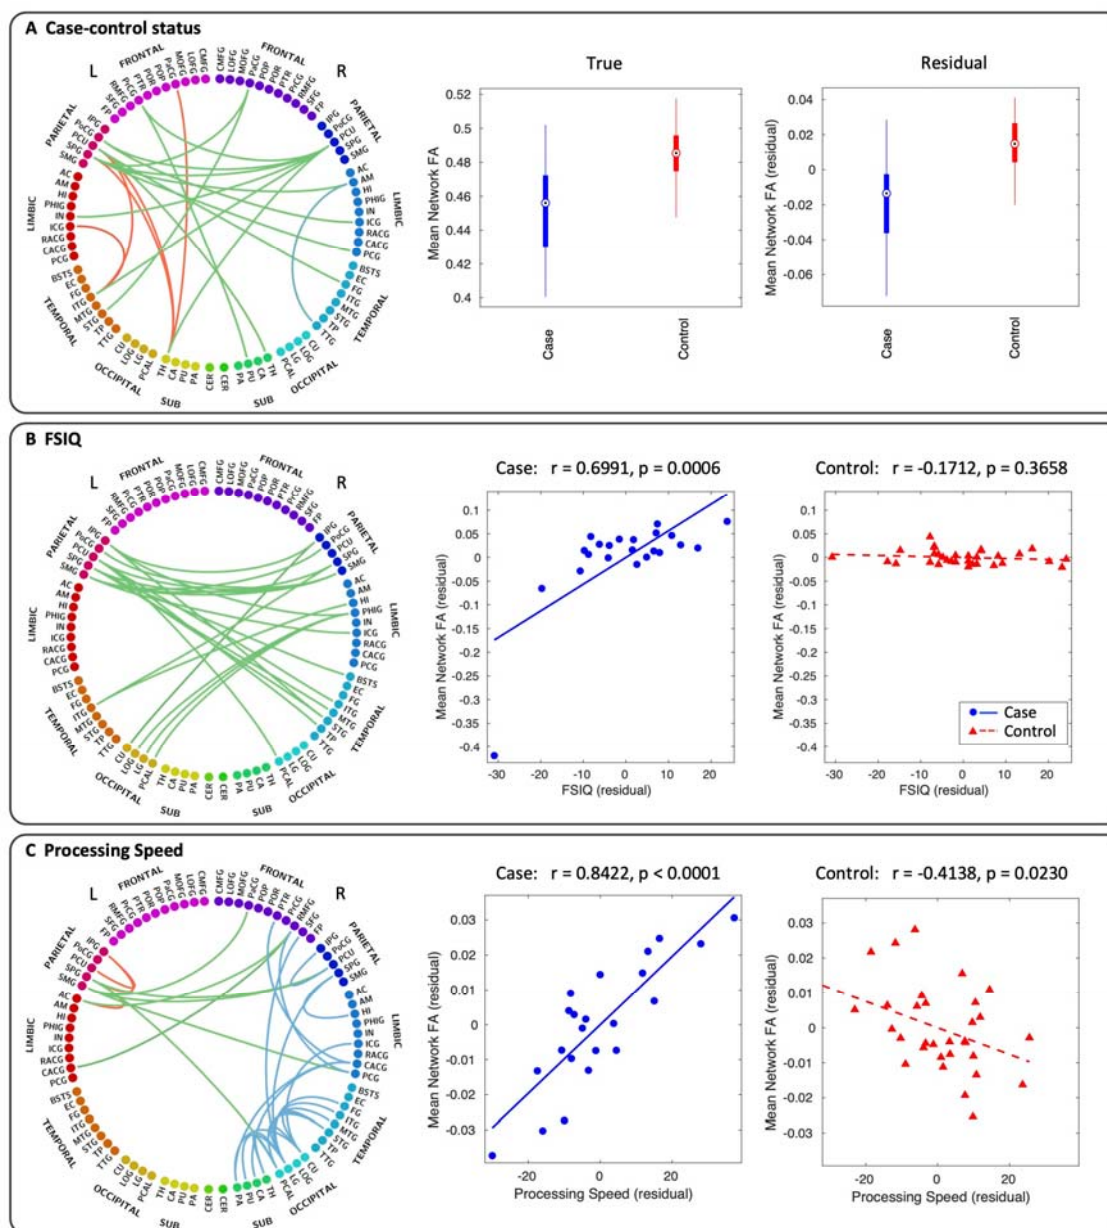

368 Figures 5 and 6 show the significant subnetworks identified by NBS. To reiterate; in each of
369 the subnetworks, the tested contrast is expressed significantly at the level of each individual
370 connection, with FWER controlled for the whole subnetwork. Significant results were found
371 for: reduced connectivity (equating to reduced FA) in cases compared to controls; stronger
372 relationship between connectivity and FSIQ in cases than in controls; and stronger
373 relationship between connectivity and processing speed in cases than in controls. No results
374 were found for group differences in the relationship between connectivity and perceptual
375 reasoning, verbal comprehension or working memory.

376

377 **Figure 5: NBS results.** Subnetworks are shown for case-control comparison (top),
378 correlation with FSIQ (middle) and correlation with processing speed (bottom). In the case-

379 control status subnetwork, all connections shown are significantly weakened in cases
 380 compared to controls (reflecting lower FA in cases). In the FSIQ and processing speed
 381 subnetworks, the dependence of cognitive score on connection strength is significantly higher
 382 in cases than in controls. The dorsal (axial) view shows all connections, while the lateral
 383 (sagittal) views of the left and right cortices show the intrahemispheric connections.

384

385 **Figure 6: Subnetworks.** Subnetworks given by NBS analysis of case-control comparison
 386 (A), correlation with FSIQ (B) and correlation with processing speed (C). Connectograms are
 387 shown with interhemispheric connections in green and intrahemispheric connections in red

388 (left) and blue (right). Panel A also shows box plots of the mean FA across all connections in
389 the case-control subnetwork for both the true FA values (left) and residual values after
390 controlling for age and sex (right). In the box plots, the circle is the median, the solid box
391 represents the 25th to 75th percentiles, and the lines extend to the minimum and maximum
392 data points. Panels B and C also show scatter plots of the mean FA across all connections in
393 the FSIQ and processing speed subnetwork, respectively, for both cases (blue circles, blue
394 solid line) and controls (red triangles, red dashed line). The complete list of node label
395 abbreviations is shown in the Supplementary Table 7.

396 Connectivity was significantly reduced in cases compared to controls ($t = 2.8$, $p = 0.0304$) in
397 a subnetwork comprising 19 nodes (10 left, 9 right) and 20 edges (14 interhemispheric, 6
398 intrahemispheric). In this subnetwork, the five most well-connected nodes were the right
399 precuneus cortex, left superior parietal gyrus, left precuneus cortex, left thalamus and left
400 inferior temporal gyrus.

401 The relationship between connectivity and FSIQ was significantly stronger in cases than
402 controls ($t = 3.5$, $p = 0.0132$) in a subnetwork comprising 23 nodes (10 left, 13 right) and 22
403 edges (all interhemispheric). The subnetwork was entirely composed of interhemispheric
404 connections connecting parietal, limbic, temporal and occipital areas. The five most well-
405 connected nodes were the left precuneus cortex, left and right supramarginal gyrus, left
406 superior parietal gyrus and right parahippocampal gyrus.

407 The relationship between connectivity and processing speed was significantly stronger in
408 cases than controls ($t = 3.3$, $p = 0.0122$) in a subnetwork comprising 28 nodes (6 left, 22
409 right) and 30 edges (7 interhemispheric, 23 intrahemispheric). The three most well-connected
410 nodes were the right lingual gyrus, left superior parietal gyrus and right cuneus cortex. See
411 Supplementary Tables 4-6 for the complete list of nodes in each subnetwork.

412 To provide graphical demonstration of each effect, the average FA in each of these
413 subnetworks was calculated for each subject and plotted as a box plot for case-control
414 differences (Fig. 6A) and plotted against FSIQ (Fig. 6B) and processing speed (Fig. 6C). This
415 figure clearly demonstrates the effect captured by each subnetwork. The median of the
416 subnetwork-averaged FA in cases was 6% lower in cases than in controls ($p < 0.0001$) in the
417 case-control status subnetwork. The dependence of FSIQ on connectivity was much stronger
418 in cases than controls in the FSIQ subnetwork (ANCOVA with age and sex as covariates; $p <$
419 0.0001). Similarly, the dependence of processing speed on connectivity was stronger in cases

420 than controls in the processing speed subnetwork (ANCOVA with age and sex as covariates;
421 $p < 0.0001$).

422 Removing the outlier in Figure 6B strengthened the correlation ($r = 0.7860$, $p < 0.0001$).

423 **4 Discussion**

424 This study assessed white matter microstructure and connectivity properties in children aged
425 6-8 years who underwent TH for NE at birth and who did not develop CP, compared to a
426 matched group of control children with no history of neurological issues. TBSS was used to
427 compare white matter microstructural properties, derived from diffusion weighted imaging
428 data at the voxel level, between cases and controls. Network analysis was used to further
429 investigate the relationship between brain connectivity and cognitive measures in cases and
430 controls, using graph theory to interpret connectome data. NBS was used to determine the
431 specific connections associated with case-control status and those associated with cognitive
432 performance.

433 Children who were treated with TH for NE at birth exhibited widespread reduction in FA
434 compared with controls. Correlations with FSIQ were found in strength, local efficiency,
435 global efficiency, clustering coefficient and characteristic path length of the structural
436 networks, in cases only. NBS revealed subnetworks associated with case-control status, FSIQ
437 and processing speed.

438 **4.1 Cases Exhibit Widespread Alterations to White Matter** 439 **Microstructure**

440 Several factors can cause a reduction in FA, including reduced fibre density, cross-sectional
441 area or myelination. Previous studies of neonates treated with TH for NE have investigated
442 the relationship between white matter diffusion properties, measured in the first weeks
443 following birth, and neurodevelopmental outcome at 2 years of age; these studies found a
444 significant reduction in FA in infants with adverse outcomes, compared to those with
445 favourable outcomes, in widespread areas of white matter including the centrum semiovale,
446 corpus callosum, anterior and posterior limbs of the internal capsule, external capsules,
447 fornix, cingulum, cerebral peduncles, optic radiations and inferior longitudinal fasciculus
448 (Lally et al., 2019; Tumor et al., 2012). In addition, FA in many of these regions was found to
449 correlate with developmental scores of children with and without CP (Tumor et al., 2012). Our
450 findings in a select group of school-age children who did not develop CP, who had

451 developmental scores in the normal range at 18 months and who were attending mainstream
452 school, demonstrated reduced FA in many of the same areas of white matter as those
453 highlighted in neonates, providing evidence that these microstructural differences persist to
454 an older age group, even in the absence of CP. This suggests that children cooled for NE have
455 an altered neurodevelopmental trajectory.

456 The question remains whether these alterations are caused by the cooling treatment, or if
457 there is residual damage from the initial injury resulting from NE. There is conflicting
458 evidence regarding the impact of TH on subcortical white matter. While one experimental
459 study reported no adverse effect of hypothermia on subcortical white matter, brain maturation
460 or neuronal death markers (Gressens et al., 2008), other studies have suggested that TH
461 causes cell death in subcortical white matter (O'Brien et al., 2019; Wang et al., 2016).
462 However, the damage resulting from NE without TH (Gao et al., 2012; Gosar et al., 2020; Ly
463 et al., 2015; van Kooij et al., 2010, 2008), and the reduction in white matter lesions with TH
464 compared to standard care following NE (Cheong et al., 2012; Rutherford et al., 2010)
465 suggest that these microstructural alterations are likely attributable to the hypoxic-ischemic
466 insult that preceded NE.

467 **4.2 Structural Connectivity Correlates with Cognitive Outcome in Cases** 468 **Only**

469 We found no significant group mean differences in the network metrics. However, when
470 considering cognitive performance, a close relationship was revealed between structural
471 connectivity and functional outcome in cases only. In controls, though each metric exhibited
472 the same general trend as in cases, none of the correlations with cognitive performance were
473 significant, indicating that individual differences in structural connectivity play a bigger role
474 in determining FSIQ in cases than in controls. The fact that this trend emerged in relation to
475 cognitive performance, despite finding no significant group differences in network metrics,
476 suggests that cases exhibit a broad spectrum of connectivity impairments, ranging from mild
477 to severe, which relate to functional outcome in these children.

478 In cases, the positive correlation of global efficiency with FSIQ and negative correlation of
479 characteristic path length with FSIQ indicate a relationship between cognitive performance
480 and network integration, which reflects the brain's ability to carry out distributed processing
481 (Bullmore and Sporns, 2009; Rubinov and Sporns, 2010). Also in cases, the positive
482 correlation of local efficiency and clustering coefficient with FSIQ demonstrate a relationship

483 between cognitive performance and network segregation, which reflects localised processing
484 capabilities (Rubinov and Sporns, 2010). These relationships provide further evidence for the
485 link between the severity of connectivity impairment and cognitive outcome following the
486 brain injury.

487 During development, increasing network segregation is thought to be associated with
488 pruning, while increasing strength and integration are thought to be associated with
489 myelination (Dennis and Thompson, 2013b; Tymofiyeva et al., 2014). We found an
490 association between reduced cognitive performance and measures of segregation and
491 integration, reinforcing the hypothesis that the developmental trajectory of the TH children is
492 altered, potentially impacting the processes of myelination and pruning and resulting in a
493 ceiling effect on functional outcome at school age.

494 Despite the association between FSIQ and network strength, efficiency, clustering and
495 characteristic path length, no relationship was found with small-worldness or modularity.
496 This suggests that brain reorganisation during development prioritises small-world, modular
497 characteristics, such that no relationship emerges between these properties and the level of
498 cognitive impairment resulting from NE. Similar findings have been reported in school-age
499 children born extremely preterm or with intrauterine growth restriction (Fischi-Gomez et al.,
500 2016).

501 **4.3 Regions Involved in Attention and Visuo-spatial Processing have** 502 **Impaired Connectivity in Cases**

503 Connectivity, measured by FA, was significantly reduced in cases compared to controls in a
504 subnetwork comprising several sensorimotor areas including the thalamus, putamen,
505 precentral gyrus, postcentral gyrus, paracentral gyrus and the superior parietal gyrus. The
506 superior parietal gyrus is concerned with aspects of attention and visuo-spatial perception,
507 including the representation and manipulation of objects. The precuneus, which appears
508 bilaterally as two of the three most well-connected nodes in the subnetwork, is associated
509 with numerous highly integrated tasks including visuo-spatial imagery and episodic memory
510 retrieval (Cavanna, 2007; Cavanna and Trimble, 2006). Other nodes in the subnetwork
511 include the insula (sensorimotor as well as higher-level cognitive function (Uddin et al.,
512 2017)), isthmus of the cingulate cortex (which has a role in memory), inferior temporal gyrus
513 (visual processing and visual object recognition), superior temporal gyrus (visual information
514 integration (Karnath, 2001; Shen et al., 2017)), fusiform gyrus (object and face recognition

515 (Kleinhans et al., 2008; Pelphrey et al., 2007)), amygdala (emotional behaviour) and the
516 posterior cingulate cortex (internally directed thought (Leech et al., 2011) and task
517 management (Pearson et al., 2011)). The posterior cingulate cortex is also involved in
518 controlling attention via interaction with the cognitive control network and has been linked to
519 attentional impairments in brain injury, autism, attention deficit hyperactivity disorder and
520 schizophrenia (Leech et al., 2011; Leech and Sharp, 2014). Both the precuneus and the
521 posterior cingulate cortex feature in the default mode network (Raichle et al., 2001),
522 suggesting a role in the neural correlates of consciousness (Cavanna, 2007).

523 The reduced connectivity to numerous regions involved in visuo-spatial processing and
524 attention aligns with behavioural findings from a study by Tonks *et al.*, demonstrating
525 reduced visuo-spatial processing, attention difficulties and slower reaction times in this group
526 of children (Tonks et al., 2019). Similarly, the sensorimotor regions included in the network
527 (in particular the numerous thalamocortical connections) may account for the reduced motor
528 performance in the absence of CP (Jary et al., 2019; Lee-Kelland et al., 2020) while the
529 impaired connectivity to the amygdala may be linked to the increased likelihood of emotional
530 behavioural difficulties (Lee-Kelland et al., 2020).

531 **4.4 Connectivity to Regions Involved in Visuo-spatial Processing** 532 **Correlates with Cognitive Outcome**

533 Subnetworks were found in which there is a stronger dependence of aspects of cognitive
534 outcome (FSIQ and processing speed) on connectivity in cases than in controls. Processing
535 speed aims to measure the mental speed and cognitive flexibility of the child; however, the
536 score is also affected by other cognitive factors such as visuo-motor coordination, visual
537 discrimination, attention, short-term visual memory and concentration. FSIQ is a measure of
538 the overall cognitive ability of an individual based on performance on all WISC-IV subtests
539 (Kaufman et al., 2006). There were no edges common to the two subnetworks, indicating that
540 the correlation with FSIQ was not driven by correlation with processing speed.

541 The most well-connected nodes in the FSIQ subnetwork are involved in visuo-spatial
542 processing, memory and attention, but there are also connections to several association
543 cortices and visual processing areas. All connections in the FSIQ subnetwork are
544 interhemispheric, suggesting involvement of the corpus callosum. The processing speed
545 subnetwork consists of predominantly visual processing regions, as well as areas involved in
546 visuo-spatial function and attention, and sensorimotor areas. Importantly, the relationship

547 between connectivity and outcome is significantly stronger in cases than in controls, as
548 demonstrated in Figures 6B and C. This provides an extension to the idea of ceiling effects
549 being imposed on the cognitive processing abilities of cases, whereby the connections in the
550 subnetwork restrict cognitive outcome in cases, whereas the cognitive processing abilities of
551 controls are less dependent on the strength of these particular connections.

552 Though perceptual reasoning, verbal comprehension and working memory were reduced in
553 cases (see Table 1), group differences in the dependence of these domains on connectivity
554 was not found. This could be due to the dependence of these domains on connectivity being
555 equal across subjects regardless of case-control status, or due to these domains being
556 dependent on different connections in each subject rather than on any distinct subnetwork.
557 This may also be dependent on how well each WISC-IV domain reflects fundamental
558 cognitive processes versus higher-level thinking.

559 **4.5 Major Hubs in the Human Connectome are Among Those Affected in** 560 **Cases**

561 Several studies have investigated structural brain network properties to determine key,
562 densely connected hub nodes which constitute a structural core, or “rich club”, of the human
563 connectome (Gong et al., 2009; Hagmann et al., 2008; van den Heuvel and Sporns, 2011).
564 These hub nodes are thought to play a central role in information integration.

565 These studies consistently identified the precuneus cortex as a key node in the rich club, as
566 well as highlighting the posterior cingulate cortex, superior parietal cortex, paracentral lobule,
567 isthmus of the cingulate cortex, superior temporal cortex and thalamus. Additionally,
568 sensorimotor areas were among those found to be hubs during the neonatal period (Fransson
569 et al., 2011; van den Heuvel et al., 2015) and have been shown to be affected in dyskinetic
570 cerebral palsy (Ballester-Plané et al., 2017), which can also result from hypoxia at birth.
571 Many of these rich club nodes were implicated in the relationship between connectivity and
572 case-control status, FSIQ and processing speed.

573 It has been suggested that, due to their topological centrality and high biological cost, rich
574 club nodes are particularly vulnerable to a wide range of pathogenic factors (Crossley et al.,
575 2014; van den Heuvel and Sporns, 2013). The high metabolic rates of the precuneus cortex
576 (Cavanna and Trimble, 2006) and posterior cingulate cortex (Leech and Sharp, 2014) support
577 this suggestion of vulnerability. Increased vulnerability may be a reason for these nodes being

578 implicated in NE children; these nodes are affected the most by the lack of oxygen during
579 birth therefore they sustain lasting developmental alterations.

580 **4.6 Strengths and Limitations**

581 To our knowledge, this is the first study to investigate whole-brain structural connectivity in
582 school-age children treated with TH for NE, who did not develop CP. We used a robust
583 methodology of high angular resolution DWI combined with an anatomically-constrained
584 tractography method capable of resolving crossing fibres. Movement can be a common issue
585 when scanning children, therefore we applied a robust quality control pipeline. The rejection
586 of scans due to movement artefact, as well as the incomplete or unobtained scans, resulted in
587 a relatively small sample size. However, there were no significant differences between the
588 cognitive scores of the rejected subjects and those included in the analysis. In order to
589 increase the robustness of the NBS results, connections were only included in the analysis if
590 expressed in >50% of cases and >50% of controls.

591 **5 Conclusions**

592 We demonstrate structural connectivity deficits relating to white matter microstructure and
593 network connectivity properties in school-age children treated with TH for NE, who did not
594 develop CP, compared to typically developing controls. We provide evidence for a
595 relationship between structural connectivity and cognitive outcome and further demonstrate
596 specific brain regions and connections which are associated with case-control status and with
597 cognitive outcome. This work demonstrates that, despite the successes of TH in reducing
598 cases of severe disability and death, there are still aspects of brain structure which are
599 impacted by the process of NE despite treatment with TH. Further study involving neonatal
600 scans and longitudinal investigation of the developmental aspects of these impairments could
601 guide follow-up care and inform future therapeutic intervention strategies.

602 **Acknowledgements**

603 We thank the children and their families for participating, Ngoc Jade Thai for her assistance
604 with MR sequences, Aileen Wilson for her radiographical expertise, and Charlotte Whitfield
605 and Emily Broadbridge for their assistance with neuropsychological assessment.
