5

6 Highlights

- 7
- Prior studies linked exposure to COVID-19 rumors with poor mental health.
- 8
- In a community sample, most participants reported having heard rumors.
- 9
- Few participants shared or believed rumors.
- 10
- Sharing sometimes occurred in the absence of belief.
- 11
- More educated individuals believed and shared fewer rumors.

12 Abstract

13 Amidst the COVID-19 pandemic, many rumors have emerged. Given prior
14 research linking rumor exposure to mental well-being, we conducted a nation-wide
15 survey to document the base rate of rumor exposure and factors associated with
16 rumor vulnerability. Between March to July 2020, 1237 participants were surveyed on
17 5 widely-disseminated COVID-19 rumors (that drinking water frequently could be
18 preventive, that eating garlic could be preventive, that the outbreak arose because of
19 bat soup consumption, that the virus was created in an American lab, and that the
20 virus was created in a Chinese lab). For each rumor, participants reported whether
21 they had heard, shared or believed each rumor. Although most participants had been
22 exposed to COVID-19 rumors, few shared or believed these. Sharing behaviors
23 sometimes occurred in the absence of belief; however, education emerged as a
24 protective factor for both sharing and belief. Together, our results suggest that
25 campaigns targeting skills associated with higher education (e.g. epistemology) may
26 prove more effective than counter-rumor messages.

29 media; infodemic; fake news

30 **Vulnerability to rumors during the COVID-19 pandemic:**

31 **Results of a national survey**

32 1. Introduction

33 The global outbreak of coronavirus disease 2019 (COVID-19) has come with
34 increased psychological burden. In several meta-analyses, depression and anxiety
35 symptoms have been found to be elevated amongst healthcare workers and the
36 general population (da Silva and Neto, 2021; Pappa et al., 2020; Salari et al., 2020).
37 Others have reported a higher incidence of stress-related symptoms or of post-
38 traumatic stress disorder (Cooke et al., 2020; Torales et al., 2020). These findings
39 highlight the urgent need to understand factors predicting psychiatric outcomes,
40 allowing vulnerable individuals to be identified and interventions to be developed.

41 In terms of predictors, exposure to COVID-19 rumors has emerged as a risk
42 factor for poor mental health (Gao et al., 2020; Liu and Tong, 2020; Vardanjani et al.,
43 2020; Xiong et al., 2020). This has occurred against the backdrop of an “infodemic” –
44 a surge of COVID-19 misinformation created and shared primarily via social media
45 (World Health Organization, 2020). In particular, the fast-changing nature of the
46 pandemic means that accurate information has not always been accessible (Cuan-
47 Baltazar et al., 2020; Hou et al., 2020), resulting in uncertainties that have given rise
48 to a large number of rumors (Depoux et al., 2020; Larson, 2018; Vosoughi et al.,
49 2018).

50 To date, several publicly-available datasets have been analyzed to document
51 the spread of rumors. For example, during the early stage of the pandemic
52 (December to April 2020), search engine keywords reflected popular myths (Rovetta
53 and Bhagavathula, 2020; Singh et al., 2020), with a large number of searches
54 pertaining to alternative medicines that had been speculated to prevent COVID-19
55 (e.g., garlic, Chinese medicinal herbs, or the malaria medication chloroquine; Hou et
56 al., 2020). On the social media platform Twitter, conspiratorial theories were posted
57 regarding disease origins – suggesting, for example, that the virus had been

58 developed as a bioweapon or had resulted from the introduction of 5G mobile
59 networks (Abd-Alrazaq et al., 2020; Ahmed et al., 2020).

60 In turn, the spread of COVID-19 rumors has led to deleterious consequences.
61 In Iran for example, a myth that alcohol consumption could prevent or treat COVID-
62 19 resulted in over 700 deaths related to methanol poisoning, with deaths attributed
63 to methanol poisoning exceeding those attributed to COVID-19 in some provinces
64 (Aghababaeian et al., 2020). Returning to mental health outcomes, the extent to
65 which an individual has been exposed to, has shared, or believed in COVID-19
66 rumors has also been found to predict anxiety symptoms (Liu and Tong, 2020).

67 While demographic predictors of pandemic-related mental health are difficult
68 to address (e.g., age, gender, pre-existing medical conditions; (Torales et al., 2020),
69 a person's exposure to rumors may constitute a modifiable risk factor (Abdoli, 2020;
70 Ebrahim et al., 2020; Holmes et al., 2020). Correspondingly, efforts to develop
71 interventions would benefit from an understanding of rumor vulnerability: (i) the base
72 rates by which individuals are exposed to, believe in, or share rumors; and (ii) factors
73 predicting these rumor-related experiences (Chua and Banerjee, 2018).

74 At present, little is known about individual vulnerability to COVID-19 rumors.
75 While a handful of studies have surveyed individuals on their social media usage and
76 enquired about rumor dissemination via these platforms (Banakar et al., 2020), we
77 are not aware of any study that has identified persons most likely to encounter,
78 believe in, or to share COVID-19 rumors. To address this gap in the literature, we
79 thus conducted a nationwide survey examining rumor vulnerability during the COVID-
80 19 pandemic.

81 2. Methods

82 2.1 Study design and population

83 Our study was conducted across five months in Singapore (7 March to 27
84 July 2020), a city-state in Asia that experienced a high number of COVID-19 cases in
85 the early stage of the pandemic. During this time, we recruited 1237 participants who

86 met the following eligibility criteria: (1) aged ≥ 21 years old, and (2) had lived in
87 Singapore for ≥ 2 years. All participants were recruited via social media
88 advertisements within community groups (e.g., groups for residential estates,
89 universities, and workplaces), or through paid Facebook advertisements targeting
90 Singapore-based users.

91 Upon study enrolment, participants provided informed consent and completed
92 a 20-minute online survey via Qualtrics. As part of a larger study, participants
93 reported their: (i) demographics, (ii) responses to the pandemic; (iii) sources of
94 COVID-19 news; and (as we report in this paper) (iv) familiarity with rumors (Liu and
95 Tong, 2020; Long and Liu, 2020; Saw et al., 2020). The study protocol was approved
96 by the Yale-NUS College Ethics Review Committee (#2020-CERC-001) and was
97 pre-registered on ClinicalTrials.gov (NCT04305574).

98 *2.2 Outcome variables*

99 As the primary outcome variables, we assessed participants' familiarity with
100 five rumors that had been widely spread during the COVID-19 pandemic: that (1)
101 drinking water frequently will help prevent infection (COVID-19 prevention); (2) eating
102 garlic can help prevent infection (COVID-19 prevention); (3) the outbreak arose from
103 people eating bat soup (COVID-19 origins); (4) the virus was created in a US lab to
104 affect China's economy (COVID-19 origins); and (5) the virus was created in a
105 Chinese lab as a bioweapon (COVID-19 origins). Rumors were selected for their
106 widespread distribution both internationally and within the local context (Taylor, 2020;
107 World Health Organisation, 2020).

108 For each rumor, participants indicated whether they: (1) had heard the claim
109 before (yes/no); (2) thought the claim was true (yes/no); or (3) had shared the claim
110 on social media (e.g., Facebook, WhatsApp) (yes/no). We assigned a score of 1 for
111 "yes" responses, and summed across the rumors to create three scores: the total
112 number of claims heard, the total number of claims believed, and the total number of

113 claims shared. Finally, participants also indicated which of 13 possible sources they
114 had encountered the rumors (e.g., Facebook, WhatsApp, online forums, television).

115 *2.3 Predictor variables*

116 As predictor variables, participants reported the following demographic
117 details: age, gender, ethnicity, religion, country of birth, marital status, education,
118 house type (a proxy of socio-economic status), and household size. Using the survey
119 time-stamp, we also recorded two situational-related variables: the total number of
120 local cases reported to date, and whether the country had been in a lock-down when
121 participants completed the survey.

122 *2.4 Statistical analysis*

123 Using counts (%), we first summarized the baseline rates of rumor familiarity
124 and rumor sources. As further exploratory analyses, we conducted Fisher's exact
125 test exploring the relationship between believing and sharing each rumor.

126 We then ran linear regression models to predict the following outcome
127 measures: the total number of claims heard [Model 1], the total number of claims
128 believed [Model 2], and the total number of claims shared [Model 3]. Each model
129 involved the full set of predictor variables (described in 2.3), with the number of
130 COVID-19 cases log-transformed for linearity.

131 For each model, we applied Bonferroni correction to control the type 1 family-
132 wise error rate at 0.05 (Bonferroni-adjusted alpha level of $0.05/22$ predictors = 0.002).

133 All statistical analyses were conducted using R (Version 4.0).

134 3. Results

135 *3.1 Response rate*

136 Out of 1751 individuals who accessed the survey link, 1446 (82.6%) provided
137 informed consent and participated in the survey. However, 209 (14.5%) participants
138 did not complete the primary outcome measures (on COVID-19 rumors) and were
139 excluded from statistical analyses.

140 The final sample of 1237 participants is comparable to the resident population
141 with regards to: the proportion of participants born in Singapore, ethnicity, and
142 household size ($\leq 10\%$ difference) and age. However, our sample had more
143 participants who were female (63.9% vs. 51.1%), single (41.9% vs 18.8%), and
144 university graduates (70.7% vs. 32.4%); and fewer participants who lived in 1-3 room
145 public housing flats (8.2% vs. 23.7%) or who had Buddhist beliefs (14.6% vs 33.2%)
146 (Table 1).

147 [Table 1 about here.]

148 3.2 Base rates of familiarity with COVID-19 rumors

149 Out of 5 widely-disseminated rumors, the average participant had heard of
150 3.34 ($SD = 1.33$) rumors. The most commonly-heard rumor – reported by 8 in 10
151 participants (84.6%) – was that the outbreak had arisen from individuals eating bat
152 soup. Despite high exposure to COVID-19 rumors, however, participants only
153 believed an average of 0.27 claims ($SD = 0.59$) and shared 0.18 ($SD = 0.63$). The
154 most commonly-believed rumor was that drinking water could prevent infection
155 (11.4%), whereas the most commonly-shared rumor was again that the disease had
156 arisen from bat soup consumption (7.1%) (Figure 1).

157 [Figures 1 and 2 about here.]

158 In other words, as shown in Figure 2, most participants who had heard each
159 of the 5 rumors neither believed in nor shared the claims. Using Fisher's exact test,
160 we conducted exploratory analyses to examine how belief and sharing behaviors
161 were related. First, for the claim about the United States manufacturing the
162 coronavirus to affect China's economy, none who shared this rumor believed that it
163 was true (p -value of 1 for Fisher's exact test). In the case of the other 4 rumors,
164 however, there was a significant association between belief and sharing ($p < 0.001$
165 for the rumors on drinking water and bat soup; $p = 0.001$ for the rumor on garlic, and
166 $p = 0.02$ for the rumor on China creating the virus). Nonetheless, even with these 4
167 rumors, not all who propagated the rumors believed that they were true.

168 Finally, Figure 3 depicts how participants had encountered COVID-19 rumors.
169 As has been previously reported (Ippolito et al., 2020; Pew Research Center, 2018),
170 social media platforms emerged as the leading sources, with 1 in 2 individuals
171 reporting exposure through Facebook (55.5%) or WhatsApp (53.6%).

172 [Figure 3 about here.]

173 *3.3 Predicting rumor hearing, sharing, and believing*

174 Model 1 examined if any demographic or situational factors predicted the
175 number of rumors heard. As shown in Table 2, participants reported hearing more
176 rumors when confirmed local cases were few (early in the pandemic) ($b = -0.621$,
177 $t(1190) = -3.588$, $p < 0.001$) or as lockdown restrictions were lifted ($b = 1.129$, $t(1190)$
178 $= 4.289$, $p < 0.001$). Additionally, there was a trend for education to predict rumor
179 exposure, with those with higher education hearing more rumors, ($b = 0.077$, $t(1190)$
180 $= 2.625$, $p = 0.009$). (However, this association was not observed when Bonferroni
181 correction was conducted.)

182 In Models 2 and 3, the same set of predictors were used to predict the
183 number of rumors shared and believed, respectively. For both these models, those
184 who were more educated shared or believed fewer rumors (Model 2: $b = -0.046$,
185 $t(1190) = -3.289$, $p = 0.001$; Model 3: $b = -0.046$, $t(1190) = -3.488$, $p = 0.001$).

186 [Table 2 about here.]

187 4. Discussion

188 During times of crisis, rumors have the potential to transmit misinformation
189 and induce anxiety (Jin et al., 2014; Tran et al., 2020). Against the backdrop of the
190 COVID-19 pandemic, we thus documented how individuals in the community came
191 to receive, believe in, or share specific COVID-19 rumors.

192 First, we observed that rumor exposure was endemic. Nearly all participants
193 had heard at least one rumor and were familiar with an average of 3 out of 5 popular
194 claims assessed. Additionally, most rumor transmission occurred via social media

195 channels (e.g., Facebook and WhatsApp), as others have noted (Islam et al., 2020;
196 Wang et al., 2019).

197 Extending previous research, we further described how the base rate of
198 believing or sharing rumors was far lower than the rate of exposure (with an average
199 of <1 rumor believed or shared). Notably, belief and sharing behaviors did not always
200 co-occur. In the extreme case of one particular rumor (that the COVID-19 crisis had
201 been manufactured by the United States), not a single participant who reported
202 forwarding the rumor actually believed in it. Although belief and sharing were linked
203 for the other rumors we assessed, there continued to be – in each case – individuals
204 who shared rumors without believing their veracity.

205 Our finding that COVID-19 rumors were disseminated even when disbelieved
206 highlights the sheer difficulty of managing the so-called ‘infodemic’. Although similar
207 findings had been reported outside the COVID-19 context (Chua and Banerjee,
208 2017), the World Health Organization and individual governments continue to issue –
209 as the prevailing strategy – fact-checking statements to debunk rumors (Wong et al.,
210 2020; World Health Organisation, 2020; Zarocostas, 2020). Our results bring to
211 question the utility of such statements, since individuals continue to share claims
212 despite perceiving them to be untrue.

213 Based on our findings, an alternative strategy may be to target individual
214 vulnerabilities instead of rumor content. Given that rumor exposure changed with
215 pandemic severity (e.g., the number of cases) and most individuals had encountered
216 COVID-19 rumors, the ensuing question is why only certain individuals fell prey to
217 either belief in or the sharing of these rumors. In our analyses, we found that
218 educational level was a consistent predictor of vulnerability: although higher
219 education predicted that an individual would hear more rumors, higher education was
220 nonetheless protective, associated with fewer rumors shared or believed in.
221 Consequently, it may be profitable to increase public awareness of knowledge and
222 skillsets associated with higher education – for example, epistemology or scientific

223 thinking (Chong et al., 2020; Chua and Banerjee, 2017) . We note, however, that the
224 correlational nature of our dataset precludes causal inferences, and further research
225 will need to examine the efficacy of such strategies in curbing pandemic-related
226 rumors.

227 *4.1 Limitations*

228 In describing these findings, we highlight several limitations of our research
229 methods. First, we relied on participants' self-reports regarding rumor exposure and
230 behaviors. Although this strategy provided individual-level information (e.g., beliefs,
231 demographics) not available in studies of actual rumor posts (e.g., when Twitter
232 posts are mined), the survey method is vulnerable to recollection and reporting
233 biases. Moving forward, future studies may opt to integrate digital documentation of
234 rumor posts alongside self-reported measures.

235 As a second limitation, we only sampled rumors that were not time-sensitive.
236 Given the limitations of the survey methodology, we could not track rumors that
237 arose from fast-changing events on the ground – for example, rumors about the first
238 COVID-19-related death in Singapore, or rumors about the availability of face masks
239 (Asokan, 2020; Ministry of Communications and Information, 2020). It thus remains
240 to be seen whether our findings can generalize to these forms of rumors.

241 *4.2 Strengths*

242 These study limitations need to be viewed alongside the putative strengths of
243 our research methodology. To the best of our knowledge, our study represents the
244 first attempt to identify individual vulnerabilities in the spread of COVID-19 rumors.
245 The research involved a large sample size (1237 participants), captured pandemic-
246 related dynamics over a long duration (5 months), and examined specific rumors that
247 had been widely disseminated.

248 *4.3 Conclusions*

249 In conclusion, our study revealed that educational level was a protective
250 factor amidst an onslaught of COVID-19 rumors. At a time when information

251 regulation is crucial to resilience and well-being (Abdoli, 2020; Garfin et al., 2020),
252 our findings provide a basis to manage the spread of rumors. In other words, it is not
253 apparent veracity that makes a rumor 'have it'. Instead, COVID-19 rumors are shared
254 even when disbelieved, but may be stemmed through higher education.

Table 1. Baseline demographics of participants

| Characteristic | N | (%) |
|--------------------------------------|----------|------------|
| Age (Mean = 39.3, SD = 12.7) | | |
| Gender | | |
| Female | 791 | (63.9) |
| Male | 445 | (36.0) |
| Did not answer | 1 | (0.1) |
| Ethnicity | | |
| Chinese | 1047 | (84.6) |
| Indian | 55 | (4.4) |
| Malay | 71 | (5.7) |
| Others | 63 | (5.1) |
| Did not answer | 1 | (0.1) |
| Religion | | |
| Buddhism | 181 | (14.6) |
| Taoism/ Chinese traditional beliefs | 51 | (4.1) |
| Islam | 71 | (5.7) |
| Hinduism | 41 | (3.3) |
| Roman Catholicism | 125 | (10.1) |
| Christianity (Protestant) | 405 | (32.7) |
| No religion | 331 | (26.7) |
| Others | 30 | (2.4) |
| Did not answer | 2 | (0.2) |
| Married status | | |
| Single | 518 | (41.9) |
| Married | 667 | (53.9) |
| Widowed/ separated/ divorced | 47 | (3.8) |
| Did not answer | 5 | (0.4) |
| Educational level | | |
| Primary school | 4 | (0.3) |
| Secondary school | 65 | (5.3) |
| Junior college | 91 | (7.4) |
| Vocational training | 22 | (1.8) |
| Polytechnic/ diploma | 154 | (12.4) |
| University (undergraduate) | 623 | (50.3) |
| University (postgraduate) | 252 | (20.4) |
| Did not answer | 26 | (2.1) |
| House type | | |
| HDB flat: 1-2 rooms | 12 | (1.0) |
| HDB flat: 3 rooms | 89 | (7.2) |

*Indicates significance at $p < .002$ (following Bonferroni corrections).

Figures and captions

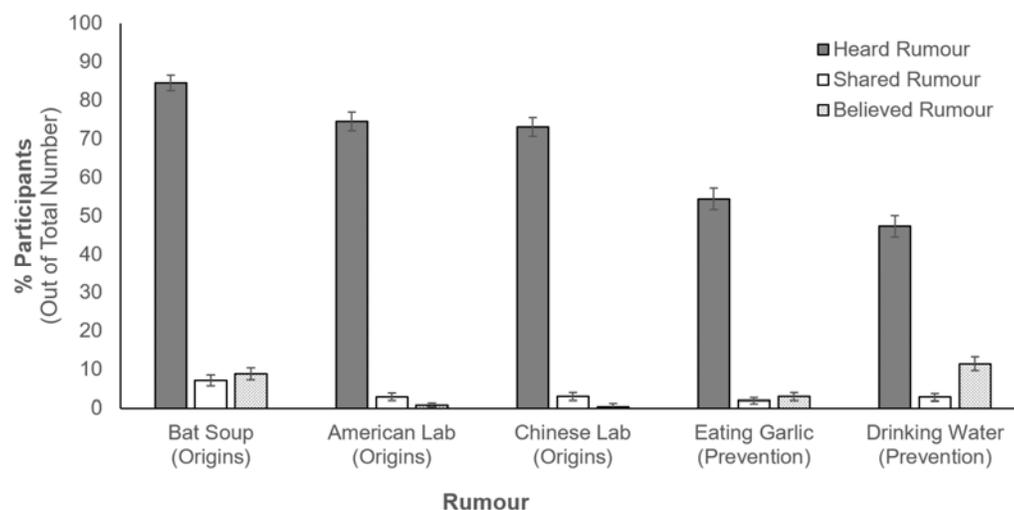

Figure 1: Proportion of participants hearing, sharing, and believe each COVID-19 rumor (that the virus originated from the consumption of bat soup, from an American lab, or from a Chinese lab; or that the virus can be cured by eating garlic or drinking water). Vertical lines represent the 95% confidence interval.)

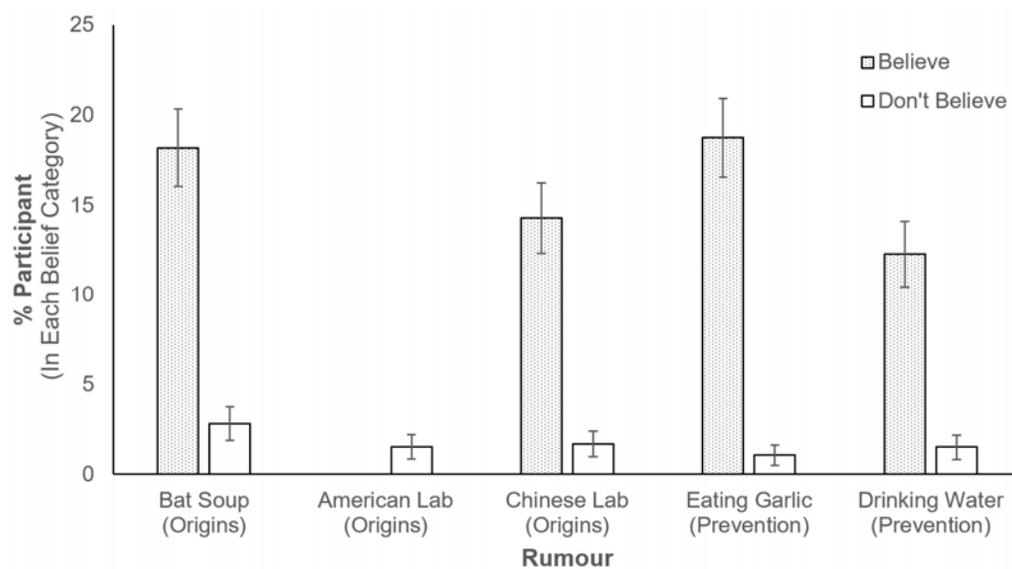

Figure 2: For each rumor, the vertical bar depicts the quantity of participants who shared each rumor, represented as a percentage of participants who believed or disbelieved each rumor. Vertical lines represent the 95% confidence interval.

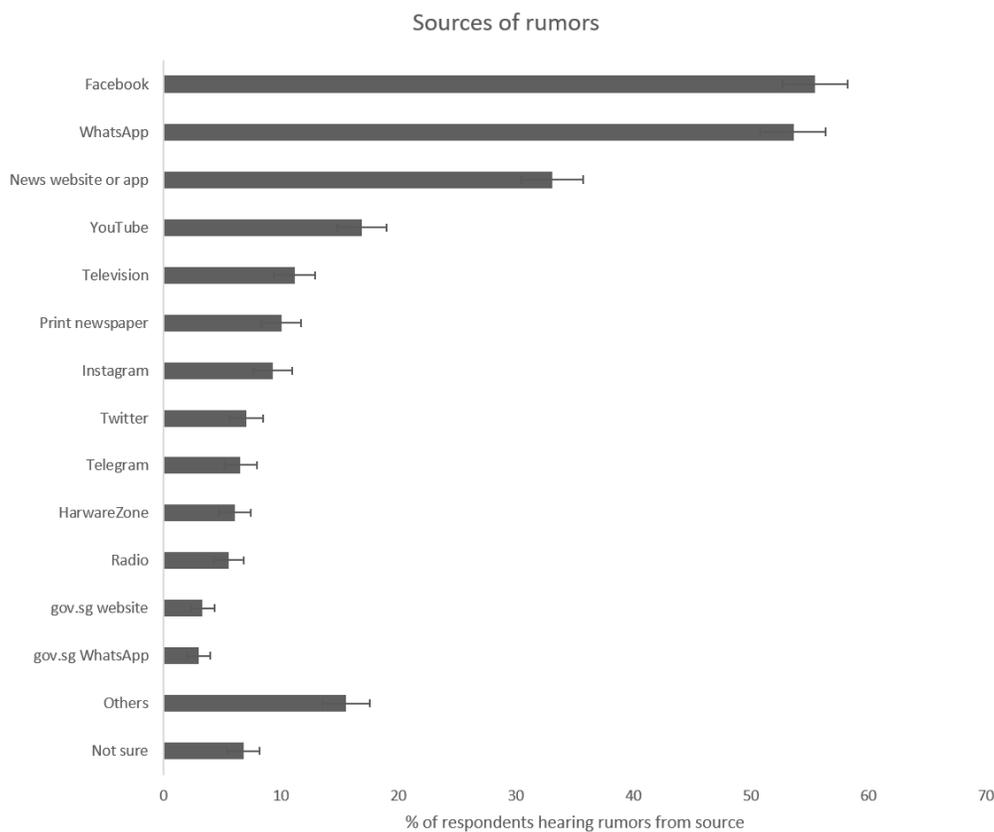

Figure 3: Sources where participants heard COVID-19 rumors from (with 95% confidence interval)
