Keywords: Eating disorder; Avon Longitudinal Study of Parents and Children

(ALSPAC); growth trajectories; body mass index; fat mass index; fat-free mass index; bone

mineral density; lean mass index.

Background: Deviating growth from the norm during childhood has been associated with anorexia nervosa (AN) and obesity later in life. In this study, we examined whether polygenic scores (PGSs) for AN and BMI are associated with growth trajectories spanning the first two decades of life. **Methods:** AN-PGS and BMI-PGS were calculated for participants of the Avon Longitudinal Study of Parents and Children (ALSPAC; N=8,654). Using generalized (mixed) linear models, we associated PGSs with trajectories of weight, height, body mass index (BMI), fat mass index (FMI), lean mass index (LMI), and bone mineral density (BMD). **Results:** Female participants with one SD higher AN-PGS had on average 0.004% slower growth in BMI between the ages 6.5-24 years and a 0.4% slower growth in BMD between the ages 10-24 years. Higher BMI-PGS was associated with faster growth for BMI, FMI, LMI, BMD, and weight trajectories in both sexes throughout childhood. Female participants with both a high AN-PGS and a low BMI-PGS showed slower growth compared to those with both a low AN-PGS and a low BMI-PGS. **Conclusion:** AN-PGS and BMI-PGS have detectable sex-specific effects on growth trajectories. Female participants with high AN-PGS and low BMI-PGS likely constitute a high-risk group for AN as their growth was slower compared to their peers with high PGS on both traits. Further research is needed to better understand how the AN-PGS and the BMI-PGS co-influence growth during childhood and whether high BMI-PGSs can mitigate the effects of a high AN-PGS.

Introduction

Anorexia nervosa (AN) is a serious psychiatric disorder that is characterized by low fat and lean mass [1–3]. Observations from genome-wide association studies (GWASs) suggest that genomic variants that influence body composition are also associated with psychiatric traits [4]. Genetically, AN is negatively correlated with body mass index (BMI), fat mass, fat-free mass, and obesity [4], suggesting that biological mechanisms contributing to AN may also influence body composition. This association is supported by several studies showing that low premorbid BMI is associated with AN in adolescence [5,6]. Furthermore, an Avon Longitudinal Study of Parents and Children (ALSPAC) study reported that individuals who go on to develop AN followed lower BMI trajectories (as early as age 2 years) compared to their peers that did not develop an eating disorder (ED) [7].

In contrast to low body weight, high body weight has not only been associated with increased risk for cardiovascular disease but also to psychiatric disorders (e.g., mood disorders and anxiety disorders) [8,9]. In addition, individuals with high body weight face stigmatization and discrimination from the public and health professionals, which can exacerbate the negative health effects of obesity [10–12]. Similar to AN, BMI has been extensively studied on a genetic level and is a heritable polygenic trait [13,14]. Khera et al. [15] reported that a BMI polygenic score (BMI-PGS), calculated by summing the BMI-increasing alleles of all variants of a BMI GWAS, weighted by their reported effect sizes [13], is associated with body weight at different timepoints during childhood and adolescence. For example, individuals with a BMI-PGS in the top decile have a modest, yet significant, higher birth weight (+60 grams) than individuals with an BMI-PGS in the bottom decile [15]. However, this difference in weight increases over time, reaching 3.5 kg by age 8 years and 12.3 kg by age 18 years [15]. These findings highlight differences in growth associated with the polygenic liability to high BMI.

In summary, both AN and BMI have a genetic component that can be summarized by

PGSs, and these genetic components are inversely correlated. However, it is unclear how

genetic risk for both traits, individually and combined, affect growth developmentally during

the first two decades of life. We identified individuals considered to be at high risk (defined

as PGS in the top two deciles) for either AN or BMI and compared them with their peers with

lower risk (defined as PGS in the lower 8 deciles) for the same trait. We then studied the

longitudinal effects of the AN-PGS [4] and the BMI-PGS [14] (separately and combined) on

weight, height, BMI, fat mass index (FMI), lean mass index (LMI), and bone mineral density

(BMD) growth trajectories during the first two decades of life using data from ALSPAC [16–

20]. We hypothesized that a higher AN-PGS would be associated with slower growth for the

weight, BMI, FMI, LMI, and BMD trajectories. Previous studies reported no genetic

correlation between height and AN and therefore we used a height trajectory as a negative

control (3). We also hypothesized that a higher BMI-PGS would be associated with faster

growth trajectories. Lastly, we hypothesized that individuals with both a high AN-PGS and

low BMI-PGS would represent a subgroup at higher risk for poor growth (slower growth)

compared to those with both a low AN-PGS and a low BMI-PGS.

Methods

Participants

The ALSPAC study is an ongoing population-based birth cohort study of 14,541 mothers and their children (that were born between 1 April 1991 and 31 December 1992) residing in the southwest of England (UK) [16–20]. From the 15,541 pregnancies, 13,988 were alive at 1 year. At age 7 years this sample was bolstered with an additional 913 children. The total sample size for analyses using any data collected after the age of seven is therefore 15,454 pregnancies; of these 14,901 were alive at 1 year of age. Participants are assessed at regular intervals using clinical interviews, self-report questionnaires, medical records, and physical examinations. Study data were collected and managed using REDCap electronic data capture tools hosted at University of Bristol [21,22]. REDCap (Research Electronic Data Capture) is a secure, web-based software platform designed to support data capture for research studies, providing 1) an intuitive interface for validated data capture; 2) audit trails for tracking data manipulation and export procedures; 3) automated export procedures for seamless data downloads to common statistical packages; and 4) procedures for data integration and interoperability with external sources. Please, note that the study website contains details of all the data that are available through a fully searchable data dictionary and variable search tool and reference the following webpage: http://www.bristol.ac.uk/alspac/researchers/our-data/. To avoid potential confounding due to relatedness, one sibling per set of multiple births was randomly selected to guarantee independence of participants - this resulted in the removal of 75 individuals. Furthermore, individuals who are closely related to each other defined as a phi hat > 0.2 (calculated using PLINK v1.90b) were removed; specifically, we removed any duplicates or monozygotic twins, first-degree relatives (parent-offspring and full siblings), and second-degree relatives (half-siblings, uncles, aunts, grandparents, and double cousins). . The authors assert that all

procedures contributing to this work comply with the ethical standards of the relevant

national and institutional committees on human experimentation and with the Helsinki

Declaration of 1975, as revised in 2008. Ethical approval for the study was obtained from the

ALSPAC Ethics and Law Committee and the Local Research Ethics Committees (Bristol and

Weston Health Authority: E1808 Children of the Nineties: ALSPAC, 28th November 1989

(for details see: www.bristol.ac.uk/alspac/researchers/research-ethics/). Informed consent for

the use of data collected via questionnaires and clinics was obtained from participants

following the recommendations of the ALSPAC Ethics and Law Committee at the time. The

main caregiver initially provided consent for child participation and from the age 16 years the

offspring themselves have provided informed written consent.

Measures

Weight, height, and body mass index (BMI). Numerous measurements of weight and

height were collected from different sources (i.e., routine clinic visits, information collected

from midwives, linkage to child health records) between birth and age 24 years. Information

on weight was collected at research clinic visits annually up to the age 14 years and further

clinic measurements at the ages 16, 18, and 24 years using the Tanita Body Fat Analyzer

(Tanita TBFUK Ltd.) to the nearest 50 grams. During the same clinic visits, height (standing)

was measured to the nearest millimeter with shoes and socks removed using a Holtain

stadiometer (Holtain Ltd, Crymych, Pembs, UK). The different measurements of weight and

height were highly correlated (**Figure S1**) across various methods [16,23]. Information on

child and adolescent BMI (weight in kilograms / height squared in meters) was derived using

weight and height measurement obtained during clinic visits.

Fat mass index, lean mass index, and bone mineral density (BMD). All ALSPAC

participants were invited to undergo a whole-body dual-energy x-ray absorptiometry (DXA)

scans using the Lunar Prodigy dual-energy X-ray absorptiometry scanner as part of face-to-

face visits at the ages of 10, 12, 14, 16, 18, and 24 years. Fat mass index was calculated by

dividing total body fat mass (in kilograms) by height (in meters) squared. Similarly, lean

mass index was calculated by dividing total lean mass divided by height (in meters) squared.

Additionally, whole-body (minus head) BMD was also estimated using the Lunar Prodigy

dual-energy X-ray absorptiometry scanner.

Trajectory modeling

Censoring for the presence of an eating disorder

To derive the trajectories for each outcome, we censored for the presence of any

eating disorder (ED); i.e., AN, bulimia nervosa, and binge-eating disorder. Information on a

probable ED was available at age 14, 16, and 18 years (see [24,25] for more information on

how ED diagnoses were derived). The presence of an ED diagnosis at age 14 years meant

that all values for that individual regarding their measurement (BMI, FMI, LMI, etc.) at age

14 years up to age 24 years were set to missing. This was also done for the presence of an ED

diagnosis at age 16 years (set values at age 16 and beyond to missing), and 18 years (set

values at age 18 and beyond to missing). Therefore, censoring did not lead to loss of

participants in the analyses, but rather loss of observations (N = 1,055). This censoring

allowed us to derive unbiased results in the following longitudinal modelling, while retaining

the largest amount of data possible. This is important, as these models are sensitive to outliers

and including individuals with EDs would likely introduce extreme values in the distribution.

*Spline modeling (**Table S1** and **Figure S2**)*

To capture the potential impact of AN on growth, we derived a BMI trajectory across

both childhood and adolescence. Prior to analyses, BMI values (**Table S1** and **Figure S2**)

were transformed using the natural log due to the right-skewed distribution of the data. Spline

models involve placing spline points (knots) at time points where the direction of growth

changes. This is necessary as children's growth in the first two decades of life is not linear,

but follows a more complex pattern, rendering standard growth models unsuitable to

accurately reflect the data [26]. The advantage of linear spline models is that they allow knot

points to be fitted at different ages to derive periods of change (between the knots) that are

approximately linear. After visual inspection of the BMI medians at each time point, two

spline points (knots), in addition to the starting point (intercept) at 4 months and the final data

wave (24 years), were placed, creating the following periods of linear growth between 4

months to age 1 year, 1 year to 6.5 years, and age 6.5 and 24 years. Mixed effects spline

models were run to describe the longitudinal growth outcomes. The mixed effects framework

lends itself to the analyses of repeated measures as it accounts for the non-independence of

measures within an individual. After fitting model fitting, we extracted parameters of slopes

using the best linear unbiased predictions (BLUPs). The linear spline modeling resulted in

three slopes (coefficients), which correspond with the slopes in the periods of growth

between age 4 months and 1 year, growth between age 1 year and 6.5 years, and growth

between age 6.5 year and 24 years. Spline models were obtained using STATA (v 15).

Genotyping

Genotype data were available for 9,915 out of the total of 15,247 ALSPAC

participants. Participants were genome-wide genotyped on the Illumina HumanHap550 quad

chip. Following quality control of the genetic data, a total of 8,654 participants with

genotyping data and at least one outcome measure were included in the analyses (**Table 1**).

Details of the quality control checks are described in the **Supplementary Information**.

PGS calculations

The AN-PGS was derived from the GWAS on AN by the Eating Disorders Working Group of the Psychiatric Genomics Consortium (PGC-ED; $n_{cases} = 16,992$, $n_{controls} = 55,525$) [4] and the BMI-PGS was derived from the BMI GWAS conducted by the Genetic Investigation of ANthropometric Traits (GIANT; n ~700,000 individuals) [14]. The datasets will be referred to as the AN and BMI discovery cohorts, respectively. The PGSs were calculated using the PRS-CS software; a method that infers posterior SNP effect sizes under continuous shrinkage (CS) priors [27].

Furthermore, we derived a categorical variable using the AN-PGS and BMI-PGS as following; we dichotomized the AN and the BMI PGS based on a cut-off value at the 8th decile of the PGS distribution. This value was selected based on previous studies that reported that individuals in top deciles of BMI-PGS and schizophrenia-PGS are at greater risk than those in lower deciles for being overweight and being diagnosed with schizophrenia, respectively [15,28]. We did not choose the highest decile as cut-off as this would have resulted in a small sample size and thus low statistical power for this particular bin. Individuals with a PGS lower than the 8th decile were grouped into a "low PGS" group, while those with a PGS score at or higher than 8th decile were grouped into a "high PGS" group. Based on this grouping, we were able to determine four categories; individuals with a (1) low PGS for AN and low PGS for BMI, (2) high PGS for AN and low PGS for BMI, (3) low PGS for AN and high PGS for BMI, and (4) high PGS for AN and high PGS for BMI. The "low AN-PGS and low BMI-PGS" group was used as the reference category in the analyses.

Statistical analyses

Univariate polygenic score analyses

In the first set of analyses, we addressed whether the AN-PGS and BMI-PGS

separately were associated with body composition trajectories. For the BMI spline trajectory,

we regressed each derived slope onto the standardized AN-PGS or the BMI-PGS and the first

four ancestry informative principal components. Data for FMI, LMI, and BMD were

measured objectively at 10, 12, 14, 16, 18, and 24 years during face-to-face visits, as

described above. For uniformity, we restricted analyses of weight and height to

measurements at these ages as growth is more linear from mid-childhood onwards. Height

was included to test the quality of methodological approach as a negative control for the

association with the AN-PGS. (3). FMI, LMI, BMD, weight, and height trajectories were

analyzed using linear mixed effects regression (LMER) using the LMER function from the

LME4 package in R [29]; the standardized AN-PGS or BMI-PGS, the first four ancestry-

informative principal components, and age were added as fixed effects. For the linear mixed

effects models, the intercept and the slope were all allowed to vary randomly across

individuals. We stratified our analyses on biological sex; phenotypic sex differences in body

composition have been reported in the general population that are detectable as early as

adolescence [30,31]. Considering that the BMI slopes are highly correlated, we additionally

corrected for slope(s) that preceded the one that is being analyzed; i.e., for the model in

which the slope between the ages 1 year and 6.5 years is the outcome we controlled for the

slope preceding this period (slope between the ages 4 months and 1 year) and for the for the

model in which the slope between the ages 6.5 year and 24 years is the outcome we

controlled for the slopes preceding this period (slope between the ages 4 months and 1 year

and the slope between ages 1 year and 6.5 years). We report for each model the beta (as a

measure of effect size, with 95% confidence intervals), and the percent change in the

estimated parameter to ease the interpretation of the beta point estimates.

Correction for multiple testing across all tests (N = 648) was done by calculating

False Discovery Rate-corrected Q-values [32]. The significance threshold was met if the

False Discovery Rate-adjusted Q was < 0.05.

Extreme group comparison of the polygenic score analyses

The effects of PGS are often most discernable in the most extreme deciles. We

therefore tested whether groups characterized by a particularly high PGS load differ from one

another. Note that this differs from testing a formal interaction between the AN-PGS and the

BMI-PGS, as our focus is on understanding the difference in growth in the extreme end of the

PGS distribution. In this second set of analyses, we used LMER to determine the association

between the body composition measures (BMI, FMI, LMI, BMD, weight, and height) and the

derived categorical AN and BMI PGS. For each regression model, the derived categorical

variable of the AN-PGS or BMI-PGS, age, and the first four ancestry informative principal

components were included as fixed effects. We included random intercepts and slope for

each individual in the model to account for variance in body composition measures that is

due to inter-individual differences. The analyses were stratified by sex, given differences in

body composition [31]. The "low AN-PGS and low BMI-PGS" group was used as the

reference category in the analyses. For this set of tests, correction for multiple testing was

done by calculating False Discovery Rate-corrected Q-values [32]. The significance threshold

was met if the False Discovery Rate-adjusted Q was < 0.05.

Post-hoc analyses of the extreme group comparisons

Based on the reported negative genetic correlations between AN and BMI [4], we also

examined whether the BMI-PGS mitigates the effect of the AN-PGS. Therefore, we carried

out post-hoc analyses, comparing the above extreme groups in order to understand how they

275 differed from one another. Post-hoc comparisons were corrected for multiple testing using

276 Tukey's adjustment.

Results

Sample Description

Following quality control of the genetic data, a total of 8,654 children with

genotyping data and at least one outcome measure were included in the analyses (**Table 1**;

Table S1; **Figure S2**).

Table 1: Descriptive data from the Avon Longitudinal Study of Parents and Children (ALSPAC). Data presented on age,

body mass index (BMI), fat mass index (FMI), lean mass index (LMI), weight, and height[a]. The sample size per outcome

varies.

Body composition measure	Age (years)	Female		Male	
		N	Median (IQR)	N	Median (IQR)
BMI (kg/m^2) [b]	10	3,072	17.31 (15.77, 19.41)	3,026	16.77 (15.61, 18.73)
	12	2,902	18.6 (16.74, 21.14)	2,797	17.96 (16.43, 20.5)
	14	2,433	20.17 (18.43, 22.58)	2,394	19.28 (17.71, 21.45)
	16	1,496	20.95 (19.47, 23.14)	1,289	20.83 (19.14, 22.78)
	18	1,986	22.14 (20.35, 24.78)	1,681	21.76 (20.08, 24.34)
	24	1,671	23.63 (21.47, 27.04)	1,131	24.25 (21.97, 27.09)
FMI (kg/m^2) [c]	10	2,932	4.4 (3.14, 6.18)	2,880	2.96 (2.08, 4.67)
	12	2,862	4.91 (3.52, 7.11)	2,750	3.65 (2.53, 5.9)
	14	2,406	5.77 (4.28, 7.74)	2,353	3.11 (2.09, 5.26)
	16	1,266	6.5 (5.00, 8.36)	1,066	2.67 (1.83, 4.14)
	18	1,895	7.13 (5.68, 9.28)	1,624	3.37 (2.22, 5.64)
	24	1,618	8.07 (6.43, 10.61)	1,100	5.7 (4.32, 7.8)
LMI (kg/m^2) [c]	10	2,932	12.07 (11.5, 12.69)	2,880	12.98 (12.43, 13.55)
	12	2,862	12.64 (11.95, 13.42)	2,750	13.28 (12.63, 14)
	14	2,406	13.39 (12.7, 14.1)	2,353	14.87 (13.9, 15.92)
	16	1,266	13.56 (12.81, 14.3)	1,066	15.93 (14.76, 16.98)
	18	1,895	13.86 (13.17, 14.64)	1,624	17.19 (16.16, 18.18)
	24	1,618	14.8 (13.95, 15.82)	1,100	17.45 (16.25, 18.83)
BMD (g/cm^2) [c]	10	2,965	0.77 (0.74, 0.81)	2,900	0.78 (0.75, 0.82)
	12	2,865	0.85 (0.8, 0.9)	2,756	0.84 (0.80, 0.89)
	14	2,406	0.96 (0.91, 1.01)	2,354	0.95 (0.90, 1.01)
	16	2,050	1 (0.96, 1.05)	1,952	1.06 (0.99, 1.12)
	18	1,902	1.04 (0.99, 1.09)	1,634	1.14 (1.08, 1.21)
	24	1,619	1.19 (1.13, 1.26)	1,101	1.32 (1.23, 1.39)
Weight (kg) [b]	10	3,105	33.6 (29.6, 38.8)	3,045	33 (29.4, 37.8)

	Age				
	12	2,904	42.8 (37, 50.2)	2,801	40.6 (35.8, 47.6)
	14	2,433	53.4 (47.8, 60.2)	2,394	53 (46.8, 61.35)
	16	1,599	57 (52, 64)	1,330	66 (59, 74)
	18	1,986	61 (55.1, 68.4)	1,683	70.4 (63.7, 79)
	24	1,671	64.9 (58.7, 75.55)	1,131	79 (70.7, 88.5)
Height (cm) [b]	10	3,074	139.05 (135, 143.4)	3,027	139.8 (135.7, 143.9)
	12	2,904	151.4 (146.4, 156.2)	2,797	149.8 (145.1, 154.7)
	14	2,438	162.1 (157.8, 166.3)	2,394	165.2 (158.9, 170.8)
	16	1,666	165 (160, 170)	1,361	178 (173, 183)
	18	1,988	165.1 (161.1, 169.2)	1,683	179 (174.45, 183.4)
	24	1,672	165.8 (161.88, 170)	1,131	180 (175.5, 184.5)

IQR = interquartile range; BMI, body mass index (weight in kilograms/height^2 in meters); FMI, fat mass index (fat mass in

kilograms/height^2 in meters); LMI, lean mass index (lean mass in kilograms/height^2 in meters); BMD, bone mineral density.

[a] Observations were censored for the presence of an eating disorder (ED); i.e., anorexia nervosa, bulimia nervosa, and binge-

eating disorder. Information on a probable ED was available at age 14, 16, and 18 years [24,25]. The presence of an ED

diagnosis at age 14 years meant that all values for that individual regarding their measurement (BMI, FMI, LMI, etc.) at age

14 years up to age 24 years were set to missing. This was also done for the presence of an ED diagnosis at age 16 years (set

values at age 16 and beyond to missing), and 18 years (set values at age 18 and beyond to missing).

[b] BMI was calculated using objectively measured weight and height during a routine clinic visit at age 24 years. Height was

measured to the nearest millimeter using a Harpenden Stadiometer (Holtain Ltd.) and weight was measured using the Tanita

Body Fat analyzer (Tanita TBF UK Ltd.) to the nearest 50 grams. To limit the size of this table only the BMI values at age

10 years and later are shown. For BMI values prior to age 10 years see Table S1.

[c] Fat mass, lean mass, and bone mineral density (BMD) were derived using a Lunar Prodigy dual emission x ray

absorptiometry (DEXA) scanner (GE Medical Systems Lunar, Madison, WI, USA). FMI and LMI were calculated by

dividing each measure (in kilograms) by height^2 (in meters). Bone mineral density (BMD) was calculated for the whole body

excluding the head values.

*Association of the AN-PGS with growth trajectories (**Table 2**)*

We observed several significant associations between the AN-PGS and growth

trajectories (on the additive scale) exclusively in the periods of linear growth in female

participants (**Table 2**). For female participants, between the ages 6.5 and 24 years, a one SD

increase in the AN-PGS was associated with a 0.004% slower growth per year in their BMI

trajectory given their BMI at 4 months (the intercept).

Furthermore, in female participants, on average a one SD higher AN-PGS was

associated with a 0.40 % slower growth per year for their BMD trajectory between the ages

10 and 24 years, given BMD at 10 years. There was no significant association between the

AN-PGS and growth trajectories in male participants.

Table 2: Associations of the anorexia nervosa polygenic score with body composition stratified for biological sex in the Avon Longitudinal Study of Parents and Children (ALSPAC) [a]

Trajectory	Parameter	Female			Male		
		Beta [b]	% change [c]	Q [d]	Beta [b]	% change [c]	Q [d]

BMI = body mass index (weight in kilograms/height^2 in meters); FMI = fat mass index (fat mass in kilograms/height^2 in meters); LMI = lean mass index (lean mass in kilograms/height^2 in meters); BMD = bone mineral density (gram/cm^2).

[a] Full description of the Avon Longitudinal Study of Parents and Children is described elsewhere; [16–20].

[b] Betas reflect one standard deviation change in the standardized (to mean zero and standard deviation of one) BMI-PGS.

[c] Considering that the outcomes were log-transformed we report the percent change in the outcome for one SD increase in the PGS to ease the interpretation of the betas.

[d] Benjamini & Hochberg False Discovery Rate adjustment for the number tests performed [32].

[e] BMI trajectory was derived using spline modeling. Prior to deriving the trajectory, BMI was transformed using the natural logarithm. For the spline modeling three spline segment (Slopes) were created: a slope capturing growth between age 4 months and 1 year; a slope capturing growth between age 1 year and 6.5 years; and a slope capturing growth between age 6.5 year and 24 years.

[f] FMI, LMI, BMD, weight, and height trajectories were analyzed using generalized linear mixed models [33]. The anorexia nervosa PGS and the first four ancestry-informative principal components were added as fixed effects. The intercept and the slope were all allowed to vary randomly across individuals.

* Significant after accounting for multiple testing using the false discovery rate-corrected Q-values. Significance was set at $Q < 0.05$.

*Association of the BMI-PGS with growth trajectories (**Table 3**)*

The BMI-PGS was associated with periods of linear growth of the BMI trajectory between the ages 1-24 years, a one SD higher BMI-PGS was associated with a 0.02% faster growth in BMI per year in female and male participants.

Between the ages 10 and 24 years, a one SD higher BMI-PGS was associated with a faster growth in FMI (16.74%), LMI (2.11%), BMD (1.64%), and weight (6.42%) in female participants. We observed no association between the BMI-PGS and the height trajectory in females. We observed a similar pattern of results in male participants with a notable exception for the FMI trajectory in which a one SD higher BMI-PGS was associated with a 20.4% faster growth in FMI between the ages 10 and 24 years.

[b] Betas reflect one standard deviation change in the standardized (to mean zero and standard deviation of one) BMI-PGS.

[c] Considering that the outcomes were log-transformed we report the percent change in the outcome for one SD increase in the PGS to ease the interpretation of the betas.

[d] Benjamini & Hochberg False Discovery Rate adjustment for the number tests performed [32].

[e] BMI trajectory was derived using spline modeling. Prior to deriving the trajectory, BMI was transformed using the natural logarithm. For the spline modeling three spline segment (Slopes) were created: a slope capturing growth between age 4 months and 1 year; a slope capturing growth between age 1 year and 6.5 years; and a slope capturing growth between age 6.5 year and 24 years.

[f] FMI, LMI, BMD, weight, and height trajectories were analyzed using generalized linear mixed models [33]. The BMI-PGS and the first four ancestry-informative principal components were added as fixed effects. The intercept and the slope were all allowed to vary randomly across individuals.

* Significant after accounting for multiple testing using the false discovery rate-corrected Q-values. Significance was set at Q < 0.05.

*Extreme group comparisons (**Figure 1**, **Table 4**)*

The effects of PGS are often most discernable in the most extreme deciles so we therefore tested whether groups characterized by a particularly high PGS load differ from one another. Note that this differs from testing a formal interaction between the AN-PGS and the BMI-PGS as our focus is on understanding difference in growth at the extreme end of the PGS distribution. For the extreme group comparisons, for the BMI trajectory, we only focused on the period of growth between the ages 6.5-24 years as the AN-PGS was only associated with this stage of growth (see **Table 2**). For the FMI, LMI, BMD, weight, and height trajectories, we analyzed the period between the ages 10-24 years. Sample sizes of the extreme group comparisons can be found in **Table S2**.

Individuals with a low AN-PGS and a high BMI-PGS followed on average faster growth than individuals with a low AN-PGS and a low BMI-PGS. The difference was most pronounced for the FMI trajectory (**Table 4**). Female participants with a low AN-PGS and a high BMI-PGS had a 27.81% faster growth in FMI compared to their peers with a low AN-PGS and a low BMI-PGS. Male participants with a low AN-PGS and a high BMI-PGS also showed faster growth in FMI (38.14%) compared to their peers with a low AN-PGS and a low BMI-PGS. Furthermore, although not statistically significant, we observed a trend in which female participants with high AN-PGS and a low BMI-PGS had slower growth for the BMI, FMI, LMI, BMD, weight, and height trajectories compared to the reference category of individuals with low AN-PGS and low BMI-PGS (**Figure 1**, **Table 4**).

*Post-hoc analyses extreme group comparisons (**Table 5**)*

In order to understand how the different PGS groups differ from one another, we conducted post-hoc analyses of the extreme group comparisons. Though the high AN-

PGS/low BMI-PGS did not differ from the reference category (**Table 4**), this group did differ (slower growth) significantly from the high AN-PGS/high BMI-PGS group and the low AN-PGS/high BMI-PGS group (**Table 5**; **Table S3**).

Figure 1: Growth trajectories for the categorial anorexia nervosa (AN) and BMI polygenic score (PGS) groups. PGS groups were derived by first dichotomizing the AN and the BMI PGS based on a cut-off value of the 8th decile of the scores. Individuals with a PGS lower than the 8th decile were grouped into a "low PGS" group, while those with a PGS score at or higher than 8th decile were grouped into a "high PGS" group. Based on this grouping we determined four categories; individuals with (1) low PGS for both AN and BMI, (2) high PGS for AN and low PGS for BMI, (3) low PGS for AN and high PGS for BMI, and (4) high PGS for both AN and BMI. **A**. Median (with 95% bootstrapped confidence interval) body mass index (BMI; weight in kilograms/height^2 in meters) trajectories across childhood and adolescence. **B.** Median (with 95% bootstrapped confidence interval) fat mass index (FMI; fat mass in kilograms/height^2 in meters) trajectories across childhood and adolescence. **C.** Median (with 95% bootstrapped confidence interval) lean mass index (LMI; lean mass in kilograms/height^2 in meters) trajectories across childhood and adolescence. **D.** Median (with 95% bootstrapped confidence interval) bone mineral density (BMD) trajectories across childhood and adolescence. **E.** Median (with 95% bootstrapped confidence interval) weight (in kilograms) trajectories across childhood and adolescence. **F.** Median (with 95% bootstrapped confidence interval) height (in centimeters) trajectories across childhood and adolescence.

[b] Only shown here are the post-hoc comparison of the PGS groups for the BMI trajectory (see also Table 4). The full results table for the remaining trajectories (fat mass index, lean mass index, bone mineral density, weight, and height) can be found in the supplementary materials (Table S3).

[c] Categorical variable derived from dichotomizing the AN-PGS and the BMI-PGS. For both the AN and the BMI PGS, individuals with PGS scores at or greater than the 8th decile point were regarded as the "high PGS group" while those with scores lower were considered the "low PGS group". From the dichotomized AN-PGS and BMI-PGS we were able to create a categorical variable with two levels (1) high AN-PGS and high BMI-PGS (2) high AN-PGS and low BMI-PGS.

[d] Post-hoc comparisons corrected for multiple testing using Tukey's adjustment.

* Significant after accounting for multiple testing.

Discussion

  Using a longitudinal data across the firs two decades of life, we report that common genomic variants associated with AN and BMI are significantly associated with growth trajectories. Female participants with a high AN genetic liability differ significantly in growth as marked by slower growth as early as age 6.5 years for the BMI trajectory and age 10 years for the BMD trajectory. This effect was not observed in male participants.

 Sex differences in body composition have been well-documented in the medical literature with men on average having more lean body mass, higher BMD, being taller, and having a lower fat mass than women [34]. These biological differences are driven by both environmental and genetic factors [31,35]. In a recent study, we reported a negative genetic correlation between body fat percentage and AN, which was significantly more pronounced in women than in men (women SNP-r_g = −0.44, SE = 0.04; men SNP-r_g = −0.26; SE = 0.04) [35]. The negative association between the AN-PGS and the BMD trajectory is consistent with the established literature that AN is phenotypically associated with BMD; AN has marked and severe adverse effects on bone metabolism [3,36]. The negative association between the AN-PGS and BMD was only found in female participants. The observed sex-specific effects of the AN-PGS suggest that a specific set of common genetic variants may be differentially active in women and may increase the liability for AN. These results also underscore the importance of collecting adequate samples from men with AN and all EDs, allowing for the calculating ED PGS specific for men, to ensure our ability to identify differential genetic effects.

 We also demonstrate that developmental changes in body composition are in part driven by the BMI-PGS as early as 4 months of age. The pattern of association of the BMI-PGS with the growth trajectories did not differ between the sexes. The BMI-PGS was significantly associated with FMI and LMI trajectories whereas the AN-PGS was not— another point of

divergence between the BMI-PGS and the AN-PGS. The association of the BMI-PGS with FMI and LMI is in part due to shared genomics [35]. In a previous study [35], we showed a significant genetic correlation between childhood BMI and adiposity (SNP-r_g = 0.46) and between childhood BMI and lean mass (SNP-r_g = 0.41). Consistent with our findings, increases in body weight are reported to be associated with higher BMD [37]. Whether these associations are due to adaptive changes of the body to increased body weight (i.e., higher BMI-PGS leads to increases in body weight, which in turn leads to increases in BMD to sustain a higher body weight) or whether this is due to shared genomics is currently unclear.

We also sought to understand how AN and BMI genetics could co-influence growth across childhood and adolescence. We found that female participants with high AN-PGS and low BMI-PGS did not significantly differ from a reference group with a low AN-PGS and low BMI-PGS, although the direction of difference aligned with expectations—individuals with high AN-PGS and low BMI-PGS have lower growth trajectories compared to the reference group. Interestingly, female participants with high genetic liability for AN and low genetic liability for BMI followed lower growth trajectories than individuals with high PGS on both traits, which might suggest that the BMI-PGS mitigated the effects of the AN-PGS. This interpretation is consistent with reports of a negative genetic correlation between AN and BMI [4,38]. Taken together, the findings from the univariate AN-PGS analyses and the findings from the extreme-group comparisons suggest that genetic liability to high weight exerts a modulating role in the association between the AN-PGS and growth trajectories. However, we cannot exclude that other PGS (e.g., depression) could also exert influence on these associations [39].

The observation that AN-PGS and BMI-PGS co-influence growth trajectories is a novel finding that encourages exploration of underlying biological mechanisms. The fact that a PGS of one trait could mitigate the effects of another trait is intriguing and has previously

been described in a study investigating stressful life events; higher well-being PGS buffered against increased depressive symptoms following a spouse's death [40]. Common genomic variants that are associated with AN or BMI are primarily expressed in the central nervous system [4,13,41], suggesting that body mass is behaviorally influenced. This view is also supported by our previous work and that of others, showing that a PGS for a higher BMI is associated with several adolescent eating behaviors including higher propensity to engage in self-reported binge eating [42–44]. Taken together, several sources of converging evidence suggest that polygenic risk for AN and/or BMI may impact growth at least in part via eating behaviors.

This study has several strengths including the large sample size and the prospective and repeated collection of objective body composition measures spanning more than 20 years. We included a negative control (i.e., the height trajectory, which was not associated with the AN-PGS), adequately controlled for multiple testing, and controlled for potential genetic confounders using ancestry informative principal components. The use of splines enabled modeling of BMI trajectories more accurately as growth throughout childhood is not linear. Further, by stratifying on biological sex, we were able to identify sex-related effects that otherwise would have been masked, and censoring on eating disorders ruled out that growth changes during puberty were a consequence of an eating disorder.

Findings from this study should be interpreted in the context of some limitations. Participants were recruited from the same geographical region in the south-west of England and, therefore, the results may not be generalizable to other populations. However, the homogeneity of this sample lends itself to genetic analyses as bias from population stratification is low [45]. Considering the longitudinal nature of the study, participants tend to drop out over time leading to missing data. We maximized available data by using mixed effects models, which allowed us to use all available data points in deriving the growth

trajectories rather than only including complete cases. We acknowledge that any bias as a consequence of missing data in our analyses could have biased our results towards the null. The effect sizes observed in this study were relatively small, but are consistent with those previously reported in other PGS studies and aid our understanding of growth trajectories [15,46]. Height and weight data in ALSPAC were obtained from a range of clinical sources, which could have introduced variability in the obtained measures. However, measures of height and weight were highly correlated across different measurement settings (clinic and self-report) (**Figure S1**). Furthermore, the BMI GWAS that was used in deriving the PGS was conducted mostly in adult participants, which could have biased our analyses. However, for BMI, a previous study found substantial overlap between childhood and adult BMI GWAS loci ($R_g = 0.76$, $P = 1.45 \times 10^{-112}$) [47]. Regarding the AN GWAS, we would like to also emphasize that both adolescents and children were included in the study; therefore, the AN GWAS should be equipped to pick up genomic variants associated with the disorder in adolescence which is the typical age of onset.

In conclusion, we show that polygenic risk for AN and BMI have detectable sex-specific effects on growth during the first two decades of life. Especially, female participants with high polygenic risk for AN and a low polygenic risk for BMI likely constitute a high-risk group as they followed lower growth trajectories, which have previously been associated with AN in the ALSPAC sample [7]. This study adds to a growing body of evidence suggesting that risk for AN could emerge during early childhood and that a combination of AN and BMI polygenic risk could aid the early identification of individuals at high risk for AN. These findings encourage further research in understanding how the AN-PGS and the BMI-PGS co-influence growth during childhood in which the BMI-PGS can amplify or mitigate the effects of the AN-PGS.

Acknowledgements

We are extremely grateful to all the families who took part in this study, the midwives for their help in recruiting them, and the whole ALSPAC team, which includes interviewers, computer and laboratory technicians, clerical workers, research scientists, volunteers, managers, receptionists and nurses.

This study represents independent research part funded by the UK National Institute for Health Research (NIHR) Biomedical Research Centre at South London and Maudsley NHS Foundation Trust and King's College London. The views expressed are those of the author(s) and not necessarily those of the UK NHS, the NIHR or the Department of Health. High performance computing facilities were funded with capital equipment grants from the GSTT Charity (TR130505) and Maudsley Charity (980). This work was supported by the UK Medical Research Council and the Medical Research Foundation (ref: MR/R004803/1). The UK Medical Research Council and Wellcome (Grant ref: 102215/2/13/2 and 217065/Z/19/Z) and the University of Bristol provide core support for ALSPAC. A comprehensive list of grants funding is available on the ALSPAC website (http://www.bristol.ac.uk/alspac/external/documents/grant-acknowledgements.pdf); This research was specifically funded by the NIHR (CS/01/2008/014), the NIH (MH087786-01). GWAS data was generated by Sample Logistics and Genotyping Facilities at Wellcome Sanger Institute and LabCorp (Laboratory Corporation of America) using support from 23andMe. NM and CB acknowledge funding from the National Institute of Mental Health (R21 MH115397). CMB is supported by NIMH (R01MH120170; R01MH124871; R01MH119084; R01MH118278; R01 MH124871); Brain and Behavior Research Foundation Distinguished Investigator Grant; Swedish Research Council (Vetenskapsrådet, award: 538-

2013-8864); Lundbeck Foundation (Grant no. R276-2018-4581). The content is solely the responsibility of the authors and does not necessarily represent the official views of the National Institutes of Health. The funders were not involved in the design or conduct of the study; collection, management, analysis, or interpretation of the data; or preparation, review, or approval of the manuscript

Conflict of interest

Dr. Breen has received grant funding from and served as a consultant to Eli Lilly, has received honoraria from Illumina and has served on advisory boards for Otsuka. Dr. Bulik is a grant recipient from and has served on advisory boards for Shire and is a consultant for Idorsia. She receives royalties from Pearson. She is on the Clinical Advisory Board of Equip Health Inc. All other authors have indicated they have no conflicts of interest to disclose.

Author Contribution

MA, CH, and MH analyzed the data. MA, CH, and MH drafted the manuscript. NM, CMB, RFL, and GB supervised the work. All authors substantially contributed to the conception and interpretation of the work, revised the manuscript for important intellectual content and approved the final version. All authors agree to be accountable for all aspects of this work.
