## HIGHLIGHTS

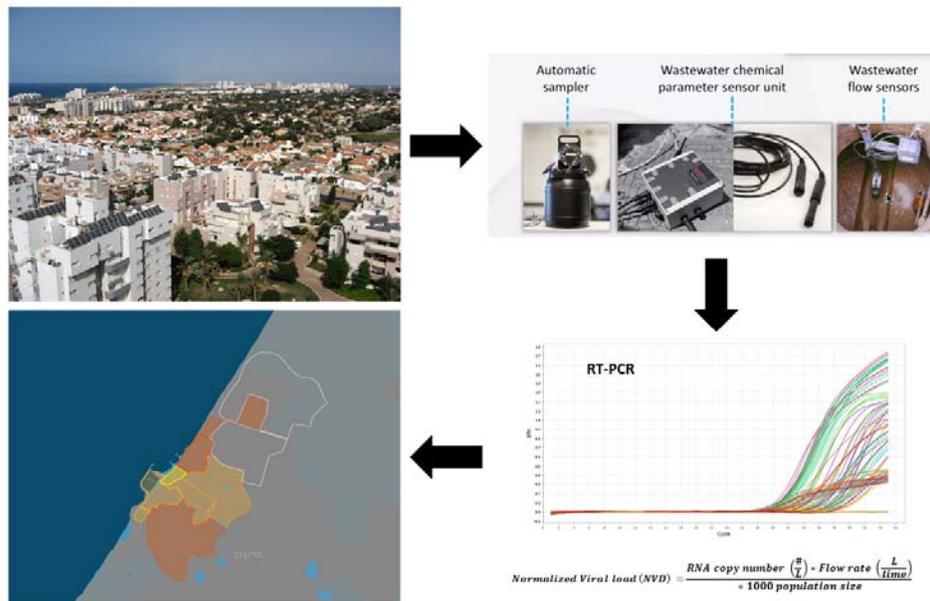

- Detecting the presence of SARS-CoV-2 virus RNA in urban wastewater
- The city sewer system may provide an early indication for SARS-CoV-2 infection and may be used as early warning for SARS-CoV-2 outbreaks
- NVL index defines various infected urban zones from red (high) to green (low)

## Abstract

The COVID-19 pandemic created a global crisis impacting not only healthcare systems, but also world economies and society. Recent data have indicated that fecal shedding of SARS-CoV-2 is common, and that viral RNA can be detected in wastewater. This suggests that wastewater monitoring is a potentially efficient tool for both epidemiological surveillance, and early warning for SARS-CoV-2 circulation at the population level. In this study we sampled an urban wastewater infrastructure in the city of Ashkelon, Israel, during the end of the first COVID-19 wave in May 2020 when the number of infections seemed to be waning. We were able to show varying presence of SARS-CoV-2 RNA in wastewater from several locations in the city during two sampling periods. This was expressed as a new index, Normalized Viral Load (NVL), which can be used in different area scales to define levels of virus activity such as red (high) or green (no), and to follow morbidity in the

population at tested area. Our index showed the rise in viral load between the two sampling periods (one week apart) and indicated an increase in morbidity that was evident a month later in the population. Thus, this methodology may provide an early indication for SARS-CoV-2 infection outbreak in a population before an outbreak is clinically apparent.

## Graphical abstract

## **Introduction**

Monitoring of urban wastewater systems can provide an efficient tool for infectious disease surveillance and can be used as an early warning system. This strategy has been used for the past decades for monitoring infectious diseases such as Polio<sup>1</sup>, antibiotic resistance<sup>2</sup> and other microbial pathogens<sup>3</sup>. SARS-CoV-2 emerged during late 2019 and has resulted in an ongoing pandemic that to date is difficult to eradicate. As vaccines are not going to be widely available soon, it is important to find novel methods for monitoring disease activity. Recent reports have shown that SARS-CoV-2 is shed through human stool<sup>5,6</sup> and can be detected in wastewater, as evident from studies worldwide<sup>7</sup>, including Israel<sup>8</sup>. Therefore, environmental surveillance of SARS-CoV-2 in sewage may provide a reliable monitoring tool for assessing disease activity and resurgence. The reliable assessment of the viral load of a population using this methodology is dependent upon many variables including the city's sewer system topology, population, and usage. This study aims to develop an urban-sewer sampling strategy for SARS-CoV-2 monitoring in different populated areas enabling geographical localization of COVID-19 outbreaks.

## **Materials and methods**

### *Sampling*

The study was performed in the city of Ashkelon, a Southern coastal city in Israel having a population of approximately 150,000 inhabitants. Ten continuous sewage-sampling units were installed in Ashkelon's wastewater system at nine selected sewer manholes and one at the inlet of the wastewater treatment plant (WWTP). The automated composite samplers were activated during two sampling campaigns, the first during 17-19 of May 2020 and the second on the 25<sup>th</sup> of May 2020. Sampling was carried out for 8 hours, from 6:00-14:00 or 07:00-15:00 at each point. The chosen sampling areas included several neighborhoods along

the coast of Ashkelon (tagged as 1 to 4 in Figure 1). The sampling points included only household wastewater. They were connected to a central sewer line that was also sampled in designated sewer junction manholes (A to E in Figure 1). This central sewer line eventually drains into the municipal WWTP (designated as point H) that treats the city wastewater. For 1 to 4 neighborhoods, the estimated population sizes were 13,500; 5,600; 2,500; 12,500 respectively, based national census data (the Central Bureau of Statistic, [https://www.gov.il/en/departments/central\\_bureau\\_of\\_statistics](https://www.gov.il/en/departments/central_bureau_of_statistics)).

Figure 1- Deployment of sampling units in the city of Ashkelon.

*Sample RNA extraction and analysis*

Raw sewage samples (1L composite sample) were immediately transferred to the lab under chilled conditions. The samples were kept at  $-20^{\circ}\text{C}$  until processed. Prior to subsampling, the bottles were shaken vigorously and left to rest for 10 minutes. Subsamples of 0.2 mL raw sewage (in duplicate) were then transferred directly into NucleoSpin RNA lysis buffer for RNA extraction (Macherey Nagel, Germany). For creating a standard curve, we used a plasmid containing the full SARS-CoV-2 N gene sequence isolated from Wuhan-Hu-1 (GenBank: NC\_045512.2). We prepared standard curves of plasmid log copy number versus Ct value using serial dilutions of the plasmid. We then performed linear regression between the log copy number and the Ct values from the RT-qPCR results. Using the linear equation, we calculated copy number of N1 gene in sewage samples reported in this study. RT-qPCR amplification was performed according to user manual recommendation using CDC's N1 and N2 primers and probe sets and One Step PrimeScript III RT-qPCR mix (TAKARA, Japan). RT-qPCR amplification was executed using Step One Plus real-time PCR system (Applied Biosystems, Thermo Scientific). In parallel to the N1 test, each RNA sample was spiked with N gene plasmid in known concentrations to rule out any amplification inhibition. A second quality control step was carried out by adding MS2 phage to the lysis buffer step as process control for RNA extraction. The analytical LOD (limit of detection) for N gene target was determined to be  $< 10$  target copies per qPCR reaction.

#### *Viral load calculation*

Viral copy number per 1L was calculated using the N1 standard curve equation (Figure S1). If Ct value for N1 was ND, then N2 Ct value was used for the calculation. A new index, namely Normalized Viral Load (NVL) was defined. It is expressing the estimated number of SARS-CoV-2 RNA copies per 1,000 people. It is based on quantification of the cumulative number of copies during several hours of composite wastewater sample collection (8 hours in

this study) in a specific location, within a steady timeframe of a day (see equation1). It can be fitted to various scales such as a street, a quarter, a small town, or a large city. Sampling location, duration, and method (preferably composite) should be unified to enable reliable use of the NVL. If the sampling is extended to 24 hours, then the NVL can be expressed as number of SARS-CoV-2 RNA copies per 1,000 people per day. Nevertheless, even sampling of several hours during a steady timeframe can serve as a reliable relative index to be assessed chronologically. This index can assist define levels of virus activity in a semi-quantitative fashion (e.g. using a ‘traffic-light’ scheme), and to follow morbidity of the population in the tested area.

$$1. \text{ Normalized Viral Load (NVL)} = \frac{\text{RNA copy number} \left(\frac{\#}{L}\right) * \text{Commulative sampling flow (L)}}{\text{Population size}/1000}$$

## Results and discussion

Ashkelon was chosen for surveillance of SARS-CoV-2 in sewage due to a relatively low COVID-19 prevalence during the time of study following a national lockdown period during April 2020 so that by beginning of May life gradually returned to normal. Ashkelon is a metropolitan area with approximately 150,000 residents. The urban sewage system design was composed from 10 continuous sewage-sampling units. During May 2020 we deployed continuous sampling devices in nine major sewer manholes in the city’s wastewater system and in the city wastewater treatment plant (WWTP). Sewage samples were tested for SARS-CoV-2 RNA and chemical analysis of these samples were performed as well including TOC, TN, and pH (see Table S1).

In this study we carried out two sampling campaigns during May 2020, a period with limited reports of COVID-19 in the city and with a very low prevalence of COVID-19 in all

of Israel. This low prevalence was achieved due to the national lockdown period during April 2020 so that by beginning of May life returned gradually to normal. Despite the fact that no new COVID-19 positive cases had been reported in Ashkelon to the Ministry of Health during this time, we found traces of the SARS-CoV-2 RNA in sewage originating from the different sampling manholes in the city (Figure 2). Figure 2a presents the accumulation of active COVID-19 cases in Ashkelon as quantified by healthcare diagnostics and reported by the ministry of health. The arrows in the figure indicate the two sampling efforts during May 2020. During the first sampling campaign, two sampling locations (A and 1) were positive for SARS-CoV-2 with normalized viral load (NVL) of  $3.63 \cdot 10^{12}$  and  $1.29 \cdot 10^{13}$  (copy number/1000 person) respectively. The remaining sampling point were negative (Not Detected, ND) including point H which is the inlet of the WWTP. These results indicate the dilution effect in the sewer system and suggests a low sensitivity of the method when sampling is applied only to the WWTP or larger geographical areas, especially when the prevalence is low and/or highly localized.

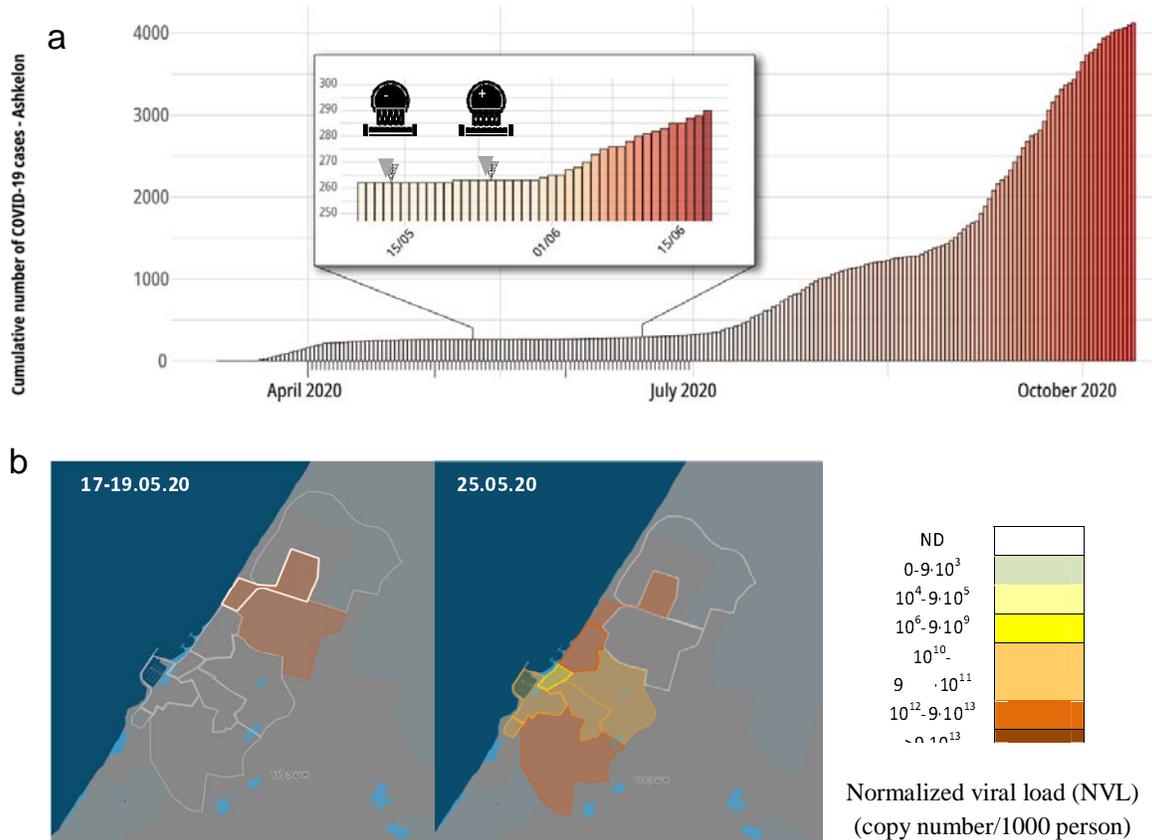

Figure 2- (a) Active COVID-19 cases in Ashkelon during March until August 2020. Black dash line presents the beginning of the second COVID-19 outbreak (reported by health care diagnostics). Arrows in the zoomed-in box, represent the sampling campaign dates in May 2020 and the illustration icons represent the SARA-CoV-2 detection results at the WWTP. (b) Normalized SARS-CoV-2 viral loads (NVL) calculated from wastewater collection campaign from different geographic locations at the city of Ashkelon.

In the second sampling campaign all sampling points were positive, with NVL between  $5.9 \cdot 10^{11}$  to  $2.77 \cdot 10^{13}$  (copy number/1000 person). Unfortunately, due to technical problem point 1 sample is missing from the second campaign. Interestingly, the viral load in point A increased by an order of magnitude from NVL of  $3.63 \cdot 10^{12}$  to  $2.77 \cdot 10^{13}$  (copy number/1000 person) between the two sampling campaigns. Figure 2b demonstrates, by color code, the NVL in each of the sampling manholes, recording the profound changes in viral load during the two sampling campaigns. While two time points are not enough to establish a trend, it is important to point out that we detected an abnormal signal about one month prior to the July COVID-19 outbreak of the second wave of in the city (seen in figure 2a). When focusing on the May sampling (Figure 2a), one can observe a relationship to reported COVID-19 cases. The low morbidity in the city reported during May, particularly at the end of the month, might have been an under estimation of COVID-19 cases due to limited testing efforts and due to asymptomatic cases (and therefore untested per testing guidelines at the time of study). The presence of the virus in the sewage despite the low prevalence reported in May attests to the sensitivity of the method. Indeed, a resurgence in COVID-19 cases became evident in the city's population in June-July 2020.

Understanding the dynamics of SARS-CoV-2 in human excreta could lead to efficient monitoring and surveillance of this virus as well as to underpin the importance of such environmental surveillance<sup>9</sup>. Our results also demonstrate the need for an inner-city sewer sampling design to overcome dilution effect that can eventually affect the sensitivity and validity of this surveillance method. Such an inner-city sewer study may assist in geographical localization of disease hotspots. Multiple sampling efforts within a city could

allow assessment of virus spread in each area and assess the proportion of areas with virus activity in a city, thus predicting imminent resurgences.

In conclusion, we present a proof-of-concept study demonstrating the feasibility of SARS-CoV-2 RNA detection in raw sewage originating from the city sewer system that reflects virus circulation in the assessed area. This approach should be further studied and validated as an early warning for SARS-CoV-2 resurgence in urban settings and as a national decision support tool<sup>10,11</sup>.

## **Supporting Information**

### *Wastewater analysis*

Raw sewage (1L composite sample) was irradiated for two hours using LP-UV lamp (7 mW/cm<sup>2</sup>, VL\_230.G, Lamp part number T-30.C, Cole Parmer Instrument Co., USA.). During the irradiation process, samples were continuously mixed in order to assure that the samples are properly inactivated. Samples were filtered through 90 mm GF/A glass fiber filter (Whatman, UK). Filtered samples were analyzed for total organic carbon (TOC) and total nitrogen (TN), using total organic carbon analyzer (TOC-V CPH, equipped with total nitrogen measuring unit, TNM-1; Shimadzu, Japan).
