17 Abstract

In 2016/2017, Washington State experienced a mumps outbreak despite high childhood vaccination rates, with cases more frequently detected among school-aged children and members of the Marshallese community. We sequenced 166 mumps virus genomes collected during outbreaks in Washington and other US states, and apply phylodynamic approaches to trace mumps introductions and transmission within Washington. We uncover that mumps was introduced into Washington at least 13 times, primarily from Arkansas, sparking multiple cocirculating transmission chains. Neither vaccination status nor age were strong determinants of

transmission. Instead, the outbreak in Washington was overwhelmingly sustained by
transmission within the Marshallese community. Our findings underscore the utility of genomic
data to clarify epidemiologic factors driving transmission, and pinpoint contact networks as
critical determinants of mumps transmission. These results imply that contact structures and
historic disparities may leave populations at increased risk for respiratory virus disease even
when a vaccine is effective and widely used.

31

32 Introduction

33 In 2016 and 2017, mumps virus swept the United States in the country's largest outbreak since 34 the pre-vaccine era (CDCMMWR, 2019). Washington State was heavily affected, reporting 889 35 confirmed and probable cases. Longitudinal studies (Davidkin et al., 2008), epidemiologic 36 outbreak investigations (Cardemil et al., 2017), and epidemic models (Lewnard and Grad, 2018) 37 suggest that mumps vaccine-induced immunity wanes over 13-30 years, consistent with the 38 preponderance of young adult cases in recent outbreaks. Like with other recent mumps 39 outbreaks, most Washington cases in 2016/17 were vaccinated. Unusually though, incidence 40 was highest among children aged 10-18 years, younger than expected given waning immunity. 41 The outbreak was also peculiar in that approximately 52% of the total cases were Marshallese. 42 an ethnic community that comprises ~0.3% of Washington's population. These same 43 phenomena were also observed in Arkansas. Of the 2,954 confirmed and probable Arkansas 44 cases, 57% were Marshallese, and 57% of cases were children aged 5-17 (Fields et al., 2019). 45 Amongst school-aged children in Arkansas and Washington, >90% had previously received 2 46 doses of MMR vaccine (Fields et al., 2019). The high proportion of vaccinated cases, younger-47 than-expected age at infection, disproportionate impact on the Marshallese community, and 48 epidemiologic link to Arkansas suggest that factors beyond waning immunity are necessary to 49 explain mumps transmission during this outbreak in Washington.

50

51	Between 1947 and 1986, the United States occupied the Republic of Marshall Islands and
52	detonated the equivalent of >7000 Hiroshima size nuclear bombs as part of its nuclear testing
53	program (Barker, 2012). The effects were devastating, precipitating widespread environmental
54	destruction, nuclear contamination, and dire health consequences (Hallgren et al., 2015;
55	Niedenthal, 1997; Palafox et al., 2007; Simon, 1997; Takahashi et al., 1997). Marshallese
56	individuals inhabiting the targeted atolls were forcibly moved to other islands, and many were
57	exposed to nuclear fallout (Abella et al., 2019) that persists on the Islands today (Bordner et al.,
58	2016). Significant concern remains within the community regarding long-term health impacts of
59	nuclear exposure and its potential impacts on immune function. Marshallese individuals living on
60	and off the Islands experience significant health disparities including a higher burden from
61	infectious diseases and chronic health conditions (Adams et al., 1986; Wong et al., 1979;
62	Yamada et al., 2004). Compounding these disparities, from 1996 to 2020 (Hirono, 2019),
63	Marshallese individuals were specifically excluded from Medicaid eligibility despite legal
64	residency in the US permitted under the Compact of Free Association (COFA) Treaty. As a
65	result, many US-residing Marshallese are uninsured, with poor access to healthcare (McElfish
66	et al., 2015). Marshallese households also tend to be larger on average (Harris and Jones,
67	2005; US Census Bureau, n.d.), potentially increasing risk for respiratory virus exposure.
68	
69	Sampling bias is a persistent challenge for elucidating source-sink dynamics during viral
70	outbreaks. Here, we formulate a set of genomic epidemiological approaches that are robust to
71	genomic sampling to investigate patterns of mumps transmission in Washington. We sequenced

72 110 mumps viral genomes obtained from specimens collected from laboratory-confirmed

- 73 mumps cases in Washington State and another 56 from other US states collected between
- 74 2006 and 2018. We employ a novel application of phylogeographic methods to detailed

- 75 epidemiologic data on age, vaccination status, and community membership, and develop a new
- 76 statistic for quantifying transmission in the tree. By combining these phylodynamic approaches
- 77 with community health advocate interviews that contextualize our results, we provide a
- 78 framework for investigating viral transmission dynamics that is sensitive to community health
- 79 priorities and readily applicable to other viral pathogens.

83 Figure 1: Washington case counts and genomic sampling

The first mumps case in Washington was reported on October 30, 2016, and case counts peaked in winter of 2017. The x-axis represents the date of the corresponding epidemiologic week, and the y-axis represents the number of confirmed and probable cases for that week. Blue dots above the case count plot represent the number of Washington genome sequences in our dataset sampled in that week.

88

89 Outbreak characteristics and dataset composition

- 90 We generated genome sequences for 110 PCR-positive mumps samples collected throughout
- 91 Washington State during 2016/2017, and 56 samples collected in Wisconsin, Ohio, Missouri,
- 92 Alabama, and North Carolina between 2006 and 2018 (Supplemental Table 1). The
- 93 Washington State outbreak began in October 2016, and peaked in winter of 2017, culminating

94 in 889 confirmed and probable cases across Washington (Fig. 1). Individuals aged <1 to 64 95 years were affected, but the highest rate of infection occurred in children aged 10-14 (44.9 96 cases per 100,000) and 15-19 (47.0 per 100,000) (Supplemental Table 2). Among individuals 97 aged 5-19 years old, 91% were considered up-to-date on mumps vaccine. Adults in the age 98 group most likely to be parents of school aged children (20-39 years old) were infected at a rate 99 of only 12.9 cases per 100.000, but comprised a significant proportion (29%) of total cases 100 (Supplemental Table 2). While Marshallese individuals comprise only ~0.3% of Washington's 101 total population, they accounted for 52% of reported mumps cases (Supplemental Table 3). 102 Among Marshallese individuals aged 5-19, 93% were up-to-date on vaccination, suggesting that 103 this over-representation is not attributable to poor vaccine coverage. 104 105 **Outbreaks across North America are related** 106 We combined our sequence data with publicly available full genome sequences sampled from 107 North America between 2006 and 2018, and built a time-resolved phylogeny, inferring migration 108 history among 26 US states and Canadian provinces (Fig. 2, Supplemental Figure 1). 109 Sequences from samples collected between 2006 and 2014 clustered with other North 110 American mumps viruses sampled from the same times. Except for 2 sequences (one from 111 Wisconsin in 2006, genotype A, and one from Washington in 2017, genotype K, both excluded 112 from Fig. 2), all samples in our dataset were genotype G viruses. Ten Washington sequences 113 were highly divergent from other North American genotype G viruses, with a time to the most 114 recent common ancestor (TMRCA) of ~22 years (Fig. 2). The remaining Washington sequences 115 nest within the diversity of other North American viruses, and descend from the same mumps 116 lineage that has circulated in North America since 2006 (Fig. 2). We observe substantial 117 geographic mixing along the tree. While viruses from Massachusetts (dark green tips and 118 branches) seeded outbreaks in the Northeast and Midwest, we also infer transmission from

Figure 2: North American mumps outbreaks are related

We combined all publicly available North American mumps genomes and built a time-resolved phylogeny. Here, we display the maximum clade credibility tree, where each color represents a unique US state or Canadian province and the x-axis represents the collection date (for tips), or the inferred time to the most recent common ancestors (for internal nodes). We inferred geographic history using a discrete trait model. The color of each internal node represents the posterior probability of the inferred geographic location, where increasingly grey tone represents decreasing probability.

119

Massachusetts to Texas, Louisiana, Alabama, and British Columbia. Despite the close
geographic proximity between British Columbia and Washington, most British Columbia
sequences form a distinct cluster on a long branch (Fig. 2), suggesting seeding from an
unsampled location. Although viruses from Washington are scattered throughout the phylogeny,
most cluster within a clade of viruses sampled in Arkansas (Fig. 2).

126 Mumps was introduced into Washington multiple independent times

127 Estimating the number and timing of viral introductions is important for estimating epidemiologic 128 parameters and evaluating surveillance networks, but is challenging with case count data alone. 129 The Washington Department of Health had identified a single potential index case in October of 130 2016. To determine whether the genomic data supported a single introduction, we separated 131 each introduction inferred in the maximum clade credibility tree and plotted each as its own 132 transmission chain (Fig. 3a). We then enumerated the number of transitions into Washington in 133 each tree in the posterior set, and plotted the distribution of Washington introductions consistent 134 with the phylogeny (Fig. 3b).

135

Figure 3: The mumps outbreak in Washington was seeded by approximately 13 introductions. We separated each introduction inferred on the maximum clade credibility tree (Figure 2) and plotted them independently. Large, colored dots represent the inferred geographic location that the Washington introduction was seeded from. Branches that extend earlier than July of 2016 are dotted to represent that

140 transmission likely occurred via other, unsampled locations. For reference, the cumulative case counts

from Arkansas and Washington are plotted below. **b.** For each tree in the posterior set, we inferred the number of introductions into Washington. We plot the proportion of trees in the posterior set in which that number of introductions was inferred.

144

145 Genomic data show that mumps was introduced into Washington State approximately 13 146 independent times (95% highest posterior density, HPD: 12 - 15), from geographically disparate 147 locations (Fig. 3). Nine sampled tips descend from long branches (~22 years), suggesting likely 148 transmission from unsampled geographic locations. We infer introductions from Ontario and 149 Missouri that each lead to 1-3 sampled cases (Fig. 3b), suggesting limited onward transmission 150 following these introductions. In contrast, 4 introductions from Arkansas account for 92/110 151 sequenced cases, suggesting that these introductions led to more sustained chains of 152 transmission following introduction (Fig. 3b). We refer to the largest cluster as the "primary 153 outbreak clade," and infer its introduction from Arkansas to Washington around August of 2016 154 (August 7, 2016, 95% HPD: July 11, 2016 to September 19, 2016, Fig. 3b), 3.5 months before 155 Washington's first reported case. These data reveal that what had appeared to be a single 156 outbreak based on case surveillance data was in fact a series of multiple introductions, primarily 157 from Arkansas, sparking overlapping and co-circulating transmission chains. 158 159 SH gene sequencing is insufficient for fine-grained geographic inference 160 Mumps virus surveillance and genotyping relies on the SH gene (Centers for Disease Control 161 and Prevention, 2019a), a short, 316 bp gene that is simple and rapid to sequence. To 162 determine whether SH gene sequencing would have produced similar results, we built a 163 divergence tree using our set of North American full genomes (Supplemental Figure 2a), then 164 truncated that data to include only SH gene sequences (Supplemental Figure 2b). Almost all 165 North American SH genes were identical, resulting in a single, large polytomy (Supplemental 166 Figure 2b). This indicates that SH sequences lack sufficient resolution to elucidate fine-grained

patterns of geographic spread, consistent with previous findings (Gouma et al., 2016; Wohl etal., 2020).

169

170 Quantifying differences in transmission patterns within Washington

171 In both Arkansas and Washington, Marshallese individuals comprised over 50% of mumps

172 cases, despite accounting for a much lower proportion of the population in both states.

173 Phylogenetic reconstruction links the outbreaks in Washington and Arkansas, placing most

174 sampled mumps genomes in Washington as descendant from Arkansas. We sought to

175 investigate how mumps transmission may have differed within Marshallese and non-

176 Marshallese communities within the same outbreak. Phylogenetic trees reflect the transmission

177 process and can be used to quantify differences in transmission patterns among population

178 groups. If transmission rates were distinct between Marshallese and non-Marshallese mumps

179 cases, we expect the following: 1. Sequences from the high-transmitting group should be more

180 frequently detected upstream in transmission chains. 2. Introductions seeded into the high-

transmitting group should result in larger and more diverse clades in the tree. 3. The internal

182 nodes of the phylogeny should be predominantly composed by members of the high-

transmitting group, while members of the low-transmitting group should primarily be found at

184 terminal nodes.

185

186 Marshallese cases are enriched upstream in transmission chains

We developed a transmission metric to quantify whether Marshallese cases were enriched at the beginnings of successful transmission chains. We traverse the full genome divergence phylogeny (**Supplemental Figure 2a**) from root to tip. When we encounter a tip that lies on an internal node, we enumerate the number of tips that descend from its parent node. We then classify each tip in the phylogeny as either having descendants or not, and compare the

192	proportion of tips with and without descendants among groups (Fig. 4a, see Methods for more
193	details). Given our sampling proportion (110 sequences/889 total cases, ~12%), we do not
194	expect to have captured true parent/child infection pairs. Rather, we expect to have
195	preferentially sampled long, successful transmission chains within the state. This allowed us to
196	assess whether infections with particular attributes (community membership, vaccination status,
197	age) are predictors for being upstream in these chains, and thus associated with sustained
198	transmission. We evaluated the probability of having descendants in the tree as a function of
199	vaccination status, age, and community status with logistic regression (see Methods for details
200	and full model). Neither age nor vaccination status were significantly associated with the
201	presence of downstream tips in the tree (Table 1). However, Marshallese cases were
202	significantly more likely to have downstream descendants than non-Marshallese cases (odds
203	ratio = 3.2, p = 0.00725, Table 1). While only 27% (14/52) of non-Marshallese tips were
204	ancestral to downstream samples, 56% (32/57) of Marshallese tips had downstream
205	descendents. These results suggest that community membership was a significant determinant

206 of sustained transmission while controlling for vaccination status and age.

	207	Table 1: Logistic	regression resul	ts of probability	y that phylogen	y nodes has	descendants
--	-----	-------------------	------------------	-------------------	-----------------	-------------	-------------

Predictor variable	Estimated coefficient (standard error)	Odds ratio (95% Cl)	p- value
Not up-to-date	-0.77 (0.69)	0.46 (0.11, 1.70)	0.26
Vaccination status unknown	0.79 (0.80)	2.21 (0.59, 9.20)	0.32
Age	-1.2 (1.44)	0.30 (0.016, 4.70)	0.41
Community status	1.17 (0.43)	3.21 (1.39, 7.69)	0.0073

We evaluated the impact of vaccination status, age, and community membership on the probability that the phylogenetic node had descendants in the tree. Coefficients represent the increase in log odds of

210 having descendants for the given predictor variable. Coefficients were exponentiated to produce odds

ratios. We evaluated the impacts of having an unknown vaccination status, having a vaccination status

that is not up-to-date, and being Marshallese as binary predictor variables. Age was evaluated as a

continuous variable normalized such that values fall between 0 and 1.

214 Longer transmission chains are associated with community status

215 In the absence of recombination, closely-linked infections will cluster together on the tree, while 216 unrelated infections should fall disparately on the tree, forming multiple smaller clusters. We 217 inferred the number of Washington-associated clades in the tree as a function of whether 218 sampled infections came from Marshallese or non-Marshallese individuals. Using the full North 219 American phylogeny, we removed all Washington sequences and separated them into viruses 220 sampled from cases noted as Marshallese or non-Marshallese. Then, separately for each 221 group, we added sequences back into the tree one by one, until all sequences for that group 222 had been added. For each number of sequences, we performed 10 independent trials (see 223 Methods for complete details), and at each step, enumerated the number of inferred 224 Washington clusters in the phylogeny. For comparison, we also grouped tips by vaccination 225 status and repeated this analysis.

226

227 For tips from non-Marshallese individuals, the number of inferred clusters increases linearly as 228 tips are added to the tree (Fig. 4b). This suggests that these infections are not directly related, 229 and are not part of sustained transmission chains (Fig. 4b). In contrast, the number of inferred 230 clusters for Marshallese tips stabilizes after ~10 tips are added, even as almost 50 more 231 sequences are added to the tree. This pattern likely arises because many Marshallese 232 infections are part of the same long transmission chain, such that newly added tips nest within 233 existing clusters. We do not observe similar differences among vaccination groups 234 (Supplemental Figure 3). These findings are consistent with distinct patterns of transmission 235 among Marshallese versus non-Marshallese cases: transmission among Marshallese 236 individuals resulted in a small number of large clusters, while transmission among non-237 Marshallese individuals are generally the result of disparate introductions that generate shorter 238 transmission chains.

240 Figure 4: Transmission chains are longer within the Marshallese community

241 a. A schematic for quantifying tips that lie "upstream" in transmission chains. For tips that lie on an 242 internal node, i.e., have a branch length of zero, we infer the number of child tips that descend from that 243 tip's parental node. For each tip in the example tree, the number of descendants we would infer is 244 annotated alongside it. All tips that have a nonzero branch length are annotated as having 0 245 descendants. We can then compare whether sequences of particular groups (here, blue vs. red) are more 246 likely to have descendants in the tree via logistic regression. b. We separated all Washington tips and 247 classified them into Marshallese and not Marshallese. We then performed a rarefaction analysis and plot 248 the number of inferred Washington clusters (y-axis) as a function of the number of sequences included in 249 the analysis (x-axis). Dark blue represents not Marshallese sequences, and light blue represents 250 Marshallese sequences. Each dot represents the number of trials in which that number of clusters was 251 inferred, and the solid line represents the mean across trials. c. The exploded tree as shown in Figure 3a 252 is shown, but tips are now colored by whether they represent Marshallese or non-Marshallese cases. For 253 reference, the number of Washington cases (y-axis) is plotted over time (x-axis), where bar color 254 represents whether those cases were Marshallese or not.

255

- 256 We next separated each Washington introduction and colored each tip by community
- 257 membership. Every introduction that was not seeded from Arkansas led to exclusively non-
- 258 Marshallese infections, while introductions from Arkansas defined lineages that circulated for
- longer and were enriched with Marshallese tips (Fig. 4c). The primary outbreak clade is
- 260 particularly enriched, containing 43 Marshallese tips and 26 non-Marshallese tips, hinting that
- transmission chains are longer when Marshallese cases are present in a cluster.
- 262

263 Mumps transmitted efficiently within the Marshallese community

264 Internal nodes on a phylogeny represent ancestors to subsequently sampled tips, while terminal 265 nodes represent viral infections that did not give rise to sampled progeny. If the mumps 266 outbreak were primarily sustained by transmission within one group, the backbone of the 267 phylogeny and the majority of internal nodes should be inferred as circulating in that group. We 268 selected the 4 introductions that contained both Marshallese and non-Marshallese tips (Fig. 4c, 269 the 4 Arkansas introductions), and reconstructed ancestral states along the phylogeny and 270 migration/transmission rates between Marshallese and non-Marshallese groups using a 271 structured coalescent model. 272 273 74/88 internal nodes were inferred to circulate within the Marshallese community with posterior 274 probability of at least 0.95 (Fig. 5a, b). Movement of a lineage from the Marshallese deme into 275 the non-Marshallese deme subsequently caused the lineage to die out quickly (Fig. 5a, dark 276 blue branches). This suggests that transmission was overwhelmingly maintained within the 277 Marshallese community, and that infections seeded into the non-Marshallese community did not 278 sustain prolonged transmission chains. We estimate substantially more transmission from 279 Marshallese to non-Marshallese groups than the opposite: within the primary outbreak clade, we 280 estimate 29 transmission events from Marshallese to non-Marshallese groups (95% HPD: 21, 281 37), and only 6 (95% HPD: 0, 14) from non-Marshallese to Marshallese groups (Fig. 5d). This 282 strongly suggests that transmission predominantly occurred in one direction: transmission 283 events leading to non-Marshallese infections usually died out, and did not typically re-seed

circulation within the Marshallese community. These results hold true regardless of migration

rate prior (Supplemental Figure 4).

286

287 Figure 5: The Washington outbreak was sustained by transmission in the Marshallese community 288 a. Using the 4 Washington clusters that had a mixture of Marshallese and non-Marshallese cases, we 289 inferred phylogenies using a structured coalescent model. Each group of sequences shared a clock 290 model, migration model, and substitution model, but each topology was inferred separately, allowing us to 291 incorporate information from all 4 clusters into the migration estimation. For each cluster, the maximum 292 clade credibility tree is shown, where the color of each internal node represents the posterior probability 293 that the node is Marshallese. **b.** For each internal node shown in panel a, we plot the posterior probability 294 of that node being Marshallese. Across all 4 clusters, 74 out of 88 internal nodes (84%) are inferred as 295 Marshallese with a posterior probability of at least 0.95. c. The posterior distribution of the number of 296 "jumps" or transmission events from Marshallese to not Marshallese (light blue) and not Marshallese to 297 Marshallese (dark blue) inferred for the primary outbreak clade. 298

- 299 To ensure that our results were not driven by unequal sampling within the analyzed clades, we
- 300 generated 3 datasets in which the number of Marshallese and non-Marshallese tips were
- 301 subsampled to be equal. For each of these 3 subsampled datasets, we ran 3 independent
- 302 chains under the same model described above. Chains converged for 2 of the 3 subsampled
- 303 datasets. In the converged chains, we recover very similar tree topologies (Supplemental
- **Figure 5a**) with equivalent phylogenetic reconstructions of lineage circulation within Marshallese

and non-Marshallese demes. We also recovered maximum clade credibility trees in which the
vast majority of the internal nodes are inferred to circulate within the Marshallese deme
(Supplemental Figure 5a,b), confirming that our findings are robust to sampling, consistent
with past observations of model performance (De Maio et al., 2015; Dudas et al., 2018;
Vaughan et al., 2014).

310

311 The structured coalescent model requires both groups to be present in each cluster, excluding 312 several small Washington introductions composed entirely of non-Marshallese tips (Fig. 4c). To 313 account for this, we used all Washington genotype G sequences in our dataset and estimated a 314 single tree using an approximate structured coalescent model (Müller et al., 2018). All 315 Washington sequences were annotated as either Marshallese or not Marshallese. To provide a 316 "source" population for the extensive diversity among our disparate Washington introductions. 317 we also specified a third, unsampled deme, for which migration was only allowed to proceed 318 outward. As above, we inferred very few non-Marshallese internal nodes (Supplemental 319 Figures 6 and 7). All internal nodes in the primary outbreak group are inferred as Marshallese 320 with high probability, while non-Marshallese cases are present as terminal nodes. We recovered 321 support for a single non-Marshallese cluster, indicating limited sustained transmission in the 322 non-Marshallese population.

323

324 Structured coalescent models infer the effective population size (N_e) for each group, which

325 reflects the number of infections necessary to generate the observed genetic diversity.

326 Differences in *N_e* can result from different transmission rates or different numbers of infected

327 individuals (Volz, 2012), and can therefore approximate differences in disease frequency

328 between groups. While the total number of Marshallese and non-Marshallese cases reported

through the public health surveillance system were similar (Supplemental Table 2), we

338	Viruses infecting vaccination groups individuals are genetically similar
337	
336	successful there and died out, resulting in short, terminal transmission chains.
335	sometimes spilled over into the non-Marshallese community, transmission was generally not as
334	sustained by transmission within the Marshallese community. While this transmission
333	Marshallese deme. Taken together, our results suggest that the outbreak was primarily
332	suggest higher transmission rates (Volz, 2012), suggesting more transmission within the
331	Marshallese group. Assuming the same number of infected individuals in each group, lower N_e 's
330	estimate that N_e for the non-Marshallese group is approximately 3 times higher than that of the

339 Although only 9.7% of reported mumps cases in Washington were not up-to-date for mumps 340 vaccination, infection of these individuals could have disproportionately impacted transmission 341 in the state. Emergence of an antigenically novel strain of mumps could also allow infection of 342 previously vaccinated individuals, and result in different virus lineages infecting individuals in 343 different vaccination categories. We colored the tips of all Washington cases in our phylogeny to 344 represent whether they were derived from individuals who were up-to-date, not up-to-date, or 345 whose vaccination status was unknown. Mirroring overall vaccination coverage in Washington, 346 the vast majority of samples in our dataset were from up-to-date individuals. The not up-to-date 347 individuals present in our dataset are dispersed throughout the phylogeny and do not cluster 348 together (Fig. 6), suggesting that there is no genetic difference between viruses infecting 349 individuals with different vaccination statuses.

Figure 6: Individuals in different vaccination groups are infected by genetically similar viruses.

The exploded tree as shown in Figure 3a is shown, but tips are now colored by whether they represent cases from individuals who are up-to-date for mumps vaccination, not upto-date, or cases for which vaccination status was unknown. The color of the large dot represents the inferred geographic location from which the Washington introduction was seeded.

350

351

352 Discussion

353 The resurgence of mumps in North America has ushered renewed attention towards

354 understanding post-vaccine era mumps transmission. While many studies have used

355 phylodynamic approaches to elucidate viral patterns of geographic spread (Dudas et al., 2017;

356 Gouma et al., 2016; Grubaugh et al., 2017; Stapleton et al., 2019), using genomics to

357 distinguish transmission patterns among epidemiologically distinct groups is novel. We employ a

358 phylogenetic method (Vaughan et al., 2014) traditionally applied to geography that is robust to

359 sampling bias (Dudas et al., 2018) to investigate drivers of mumps transmission in Washington.

- 360 We show that the Washington State outbreak was fueled by approximately 13 independent
- 361 introductions, primarily from Arkansas, leading to multiple co-circulating transmission chains.

362 Within Washington, transmission was more efficient within the Marshallese community. 363 Marshallese individuals were more often sampled at the beginnings of transmission chains. 364 contributed to longer transmission chains on average, and were overwhelmingly enriched on 365 internal nodes within the phylogeny. We found no support for age or vaccination status as 366 critical determinants of transmission in our outbreak, consistent with epidemiologic findings. Our 367 data suggest that social networks can be critical determinants of mumps transmission. Future 368 work exploring how social and economic disparities may amplify respiratory disease 369 transmission will be necessary for updating outbreak mitigation and prevention strategies. By 370 combining detailed metadata, novel metrics of transmission in the tree, and robust controls for 371 sampling, we provide a framework for investigating source-sink dynamics that are readily 372 applicable to other viral pathogens.

373

374 Our results highlight the utility of genomic data to clarify epidemiologic hypotheses. While 375 genomic data and epidemiologic investigation (including case interviews and contact follow up) 376 suggested an Arkansas introduction as the Washington outbreak's primary origin, sequence 377 data revealed repeated and ongoing introductions into Washington, similar to patterns observed 378 in Massachusetts, and the Netherlands (Gouma et al., 2016; Wohl et al., 2020). We also find 379 widespread geographic mixing across the phylogeny, consistent with investigations from the US 380 (Wohl et al., 2020), Canada (Stapleton et al., 2019), and Europe (Gavilán et al., 2018; Gouma et 381 al., 2016). Like others (Gouma et al., 2016; Wohl et al., 2020), we confirm that SH genotyping 382 alone is insufficient for fine-grained resolution of geographic transmission patterns. While CDC 383 guidelines currently recommend SH-based genotyping specifically for tracking transmission 384 pathways (Clemmons et al., 2020), building public health capacity for full-genome sequencing 385 may provide better resolution for resolving local mumps transmission patterns.

386

387 Despite similar numbers of Marshallese and non-Marshallese cases, we find that mumps did not 388 transmit efficiently among the general Washington populace. Washington State uses a passive 389 surveillance system for mumps detection and case acquisition, which are known to frequently 390 result in underreporting. Because the WA Department of Health did not perform active mump 391 surveillance, it is difficult to assess whether different epidemiologic groups have different 392 likelihoods of being sampled. Marshallese individuals are less likely to seek healthcare (Towne 393 et al., 2020), which may have resulted in particularly high rates of underreporting in this group. 394 Although statewide vaccine coverage is high, the risk for acquiring and transmitting mumps is 395 clearly not equal across all Washington population groups. Provision of an outbreak dose of 396 mumps-containing vaccine to high-risk groups may therefore be especially effective for limiting 397 mumps transmission in future outbreaks. Others have reported success in using outbreak dose 398 mumps vaccinations to reduce mumps transmission on college campuses (Cardemil et al., 399 2017; Shah et al., 2018) and in the US army (Arday et al., 1989; Eick et al., 2008; Green, 2006; 400 Kelley et al., 1991), and the CDC currently recommends providing outbreak vaccine doses to 401 individuals with increased risk due to an outbreak (Marlow et al., 2020). Future work to quantify 402 the interplay between contact rates and vaccine-induced immunity among different age and risk 403 groups should be used to guide updated vaccine recommendations.

404

Recent research has focused on identifying groups at risk for mumps infection due to their age (Lewnard and Grad, 2018), with less attention to other factors that may make populations vulnerable. In the 2016/017 Washington State outbreak, Marshallese status was a crucial predictor of transmission risk. Mumps has historically caused outbreaks in communities with strong, interconnected contact patterns (Barskey et al., 2012; Fields et al., 2019; Nelson et al., 2013), and in dense housing environments (Snijders et al., 2012). While a combination of waning immunity and dense housing settings make college campuses ideal for mumps

412 outbreaks, the Washington and Arkansas outbreaks show that populations other than young 413 adults are at risk. Soliciting feedback from a Marshallese community health advocate allowed us 414 to contextualize our genomic results with the lived experience of individuals most heavily 415 affected during the outbreak and to identify reasonable hypotheses to explain the efficient 416 transmission we observe. Based on these interviews and previously published studies, we 417 speculate that within the Marshallese community, a combination of factors likely led to a high 418 force of infection.

419

420 Multigenerational living is common in the Marshallese community (Fields et al., 2019), and 421 Marshallese households tend to be larger on average (average household size = 5.28 (Harris 422 and Jones, 2005), average household size for entire US populace = 2.52 (US Census Bureau, 423 n.d.)). Having more household contacts may have facilitated a greater number and higher 424 intensity of interactions among individuals, allowing the force of infection to overcome pre-425 existing immunity. It is also possible that infection intensity within the Marshallese community 426 was exacerbated by low rates of insurance coverage and poor access to healthcare (McElfish et 427 al., 2017; Towne et al., 2020), hesitancy to seek medical care (Williams and Hampton, 2005), 428 and health disparities stemming from US occupation, nuclear testing, and exclusion from 429 healthcare services. As part of reparations for US nuclear testing, the US signed the Compact of 430 Free Association Treaty (COFA)(Congress, 2003) with the Marshall Islands in 1989, permitting 431 Marshallese residents to live and work in the US without visas. However, eligibility for Medicaid 432 was revoked for COFA immigrants in 1996, and US-residing Marshallese remain economically 433 disadvantaged and under-insured (McElfish, 2016; McElfish et al., 2017, 2015). The passage of 434 the Affordable Care Act (ACA) has not ameliorated these issues. Interviews with US-residing 435 Marshallese note confusion among ACA staff regarding the legal status of COFA recipients, 436 leading to drawn out enrollment processes that often leave individuals uninsured, frustrated

437 (McElfish et al., 2016), and far less likely to access care (Towne et al., 2020). A study of 438 healthcare-seeking behavior among patients with diabetes showed that while multiple factors 439 contribute to forgone care in the US populace, 77% of surveyed Marshallese individuals 440 reported recent forgeone care and cited lack of insurance as the primary reason (Towne et al., 441 2020). Marshallese trust in US medical institutions was seriously undermined by the 442 unconsented use of Marshallese individuals for experiments on health impacts of nuclear 443 exposure, with effects lingering today (Barker, 2012). Banked historical samples confirm uptake 444 of radioactive materials in Marshallese inhabitants of affected Islands (Simon et al., 2010), but 445 there has been limited published data on long-term health impacts of nuclear exposure, and 446 significant concern remains within the community (Bordner et al., 2016). Finally, when 447 Marshallese individuals do access care, they report experiencing disdain from healthcare 448 workers (Duke, 2017) and sub-optimal care (McElfish et al., 2016). Interviews with medical 449 workers show that blame for poor Marshallese health outcomes is sometimes placed on host 450 genetics or cultural practices (Duke, 2017), poor health literacy (McElfish et al., 2018), or 451 choosing to delay care (McElfish et al., 2018), with less consideration given to how the 452 economic and legal impacts of US occupation affect the health of Marshallese individuals. 453 These factors compound, and Marshallese individuals report hesitation to seek medical care, 454 even when sick (McElfish et al., 2016). Hesitancy to seek care could have contributed to mumps 455 transmission if sick individuals were primarily cared for at home without knowledge of or the 456 ability to implement community-isolation protocols.

457

Our findings highlight that social networks can be the primary risk factor for a respiratory virus
outbreak, even when a vaccine is effective and widely used. This finding is especially pertinent
as SARS-CoV2 continues to disproportionately impact populations who live and work in highrisk settings, including the Marshallese (Center et al., 2020; McElfish et al., 2021), and for whom

462 vaccine licensure and distribution alone may not be a panacea. The passing of federal 463 legislation remedying the exclusion of Marshallese individuals from Medicaid access (Hirono, 464 2019) in December 2020 marks an important step toward improving healthcare access for US-465 residing Marshallese. Future work to evaluate whether this change improves Marshallese 466 access to healthcare and mitigates increased disease risk will be crucial follow-up. Future work 467 should also explore whether nuclear exposure has impacted Marshallese immune function and 468 susceptibility to infectious disease. Our findings demonstrate the importance of expanding our 469 understanding of populations at risk for mumps re-emergence, so that rapid and comprehensive 470 outbreak response strategies can be implemented to mitigate negative health impacts for all 471 affected communities. Finally, future work to disentangle the complex interplay between 472 healthcare access, social and economic disparity, and respiratory virus risk will be essential for 473 mitigating health impacts of mumps and other respiratory viruses. 474 475 476 **Materials and Methods** 477 478 **Data and Code Availability** 479 All code used to analyze data, input files for BEAST, and all code used to generate figures for 480 this manuscript are publicly available at https://github.com/blab/mumps-wa-phylodynamics. Raw 481 FASTQ files with human reads removed are available under SRA project number 482 PRJNA641715. All protocols for generating sequence data as well as the consensus genomes 483 are available at https://github.com/blab/mumps-seg. Consensus genomes have also been 484 deposited to Genbank under accessions MT859507-MT859672. 485

486 **Community feedback**

487 In order to ensure that this study was faithful to the experience of the Marshallese community in 488 Washington State, we sought paid consultation from a local Marshallese community health 489 advocate. We conducted video and telephone interviews to directly address the impacts of 490 mumps transmission on the Marshallese community, community healthcare goals and priorities, 491 and the impacts of the mumps outbreak on stigmatization. This feedback informed what is being 492 presented herein, provided crucial context for understanding mumps transmission, and allowed 493 us to work with the community to determine how best to discuss Marshallese involvement in the 494 outbreak. 495 496 Mumps surveillance in Washington State 497 Mumps is a notifiable condition in Washington State. Therefore, per the Washington 498 Administrative Code (WAC), as specified in WAC Chapter 246-101(Washington State 499 Legislature, 2014), healthcare providers, healthcare facilities, and laboratories must report 500 cases of mumps or possible mumps to the local health jurisdiction (LHJ) of the patient's 501 residence. LHJ staff initiate case investigations and facilitate optimal collection and testing of

502 diagnostic specimens. Buccal swabs and urine are acceptable specimens for real-time reverse

transcription polymerase chain reaction (qRT-PCR), a preferred diagnostic test for mumps. Most

504 mumps rRT-PCR tests for Washington State residents are performed at the Washington State

505 Public Health Laboratories, where all positive specimens are archived.

506

507 Individuals testing positive for mumps ribonucleic acid (RNA) by qRT-PCR are classified as

508 confirmed mumps cases if they have a clinically-compatible illness (i.e., an illness involving

509 parotitis or other salivary gland swelling lasting at least 2 days, aseptic meningitis, encephalitis,

510 hearing loss, orchitis, oophoritis, mastitis, or pancreatitis). During case investigations, case-

511 patients or their proxies are interviewed. Information about demographics, illness 512 characteristics, vaccination history, and potential for exposure to and transmission of mumps 513 are solicited from each case-patient. In concordance with CDC guidelines (Centers for Disease 514 Control and Prevention, 2019b), only vaccine doses for which there was written documentation 515 with the date of vaccine receipt were considered valid. Individuals for which such documentation 516 could not be provided were classified as having an unknown vaccination status. For individuals 517 with documented vaccine doses, they were further characterized as up-to-date or not up-to-date 518 based on their age. The Washington State Department of Health (DOH) receives, organizes, 519 performs quality control on, and analyzes data from, LHJ case reports and supports 520 investigations upon request. 521 522 Sample collection and IRB approval 523 This study was approved by the Fred Hutchinson Cancer Research Center (FHCRC) 524 Institutional Review Board (IR File #: 6007-944) and by the Washington State Institutional 525 Review Board, and classified as not involving human subjects. Samples were selected for 526 sequencing to maximize temporal and epidemiologic breadth and to ensure successful 527 sequencing. As such, samples were chosen based on the date of sample collection, the PCR 528 cycle threshold (Ct), case vaccination status, and community status (Marshallese or non-529 Marshallese). Samples were selected for sequencing in 2 batches. In the first, samples were 530 selected based on covering a wide geographic range within Washington, a full range of dates 531 covering the outbreak, and having a Ct value < 36. This initial sampling regime resulted in a 532 sample set skewed slightly towards samples from Marshallese individuals. To ensure that the 533 proportion of samples in our data closely matched the distribution of cases in the outbreak, we 534 then selected a second batch of samples using the same criteria as above, but excluded 535 samples from Marshallese individuals. We then randomly sampled an additional 30 samples

536	from non-Marshallese individuals. This sampling regime resulted in a dataset that closely
537	mirrors the distribution of metadata categories in the outbreak overall. All metadata, including
538	case vaccination status, were transferred from WA DOH to FHCRC in a de-identified form.
539	
540	We also sequenced an additional set of 56 samples collected in Wisconsin, Ohio, Missouri,
541	Alabama, and North Carolina provided by the Wisconsin State Laboratory of Hygiene. 10 of
542	these samples were collected in Wisconsin during the 2006/2007 Midwestern college campus
543	outbreaks, 6 samples were collected in 2014, and the rest were collected between 2016 and
544	2018. For these samples, we received metadata describing sample Ct value and date of
545	collection. All metadata were received by FHCRC in de-identified form.
546	
547	Viral RNA extraction, cDNA synthesis, and amplicon generation
548	Viral RNA was extracted from buccal swabs using either the QiAmp Viral RNA Mini Kit (Qiagen,
549	Valencia, CA, USA) or the Roche MagNA Pure 96 DNA and viral NA small volume kit (Roche,
550	Basel, Switzerland). For samples extracted with the QiAmp Viral RNA Mini Kit, 500 μl of buccal
551	swab fluid was spun at 5000 x g for 5 minutes at 4° C to pellet host cells. The supernatant was
552	then removed and centrifuged at 14,000 rpm for 90 minutes at 4°C to pellet virions. Excess fluid
553	was discarded, and the peletted virions were resuspended in 150-200 μI of fluid. Resuspended
554	viral particles were then used as input to the QiAmp Viral RNA Mini Kit (Qiagen, Valencia, CA,
555	USA), following manufacturer's instructions, and eluting in 30 μl of buffer AVE. For extraction
556	with the MagNA Pure, we followed manufacturer's instructions.
557	
558	cDNA was generated with the Protoscript II First strand synthesis kit (New England Biolabs,
559	Ipswich MD, USA), using 8 μ I of vRNA as input and priming with 2 μ I of random hexamers.

560 vRNA and primers were incubated at 65°C for 5 minutes. Following this incubation, 10 μ l of

Protoscript II reaction mix (2x) and 2 µl of Protoscript II enzyme mix (10x) were added to each
reaction and incubated at 25°C for 5 minutes, then 42°C for 1 hour, followed by a final
inactivation step at 80°C for 5 minutes. To amplify the full mumps genomes, we used Primal
Scheme (<u>http://primal.zibraproject.org/</u>) to design overlapping, ~1500 base pair amplicons
spanning the entirety of the mumps virus genome, where each tiled set of primes overlapped by
~100 base pairs. Primers are listed below.

Primer	Primer sequence	Forward/Reverse	Primer pool
mumps_1.5kb_1F	ACCAAGGGGAAAATGAAGATGGG	Forward	pool 1
mumps_1.5kb_1R	TAACGGCTGTGCTCTAAAGTCAT	Reverse	pool 1

568

569

570 Primers were pooled into 2 pools as follows: the first contained primer pairs 1, 3, 5, 7, 9, and 11,

all pooled at 10 uM. The second pool contained primer pairs 2, 4, 6, 8, 10, and 12. All primers in

572 pool 2 were pooled at 10 uM, except for primer pair 4, which was added at a 20 uM

573 concentration.

575 PCR was performed with the Q5 Hotstart DNA polymerase (New England Biolabs, Ipswich, 576 MD, USA), using 11.75 µl of nuclease-free water, 5 µl of Q5 reaction buffer, 0.5 µl of 10 mM 577 dNTPs, 0.25 µl, 2.5 of pooled primers, and 5 µl of cDNA. Amplicons were generated with the 578 following PCR cycling conditions: 98°C for 30 seconds, followed by 30 cycles of: 98°C for 15 579 seconds, then 67°C for 5 minutes. Cycling was concluded with a 10°C hold. PCR products were 580 run on a 1% agarose gel, and bands were cut out and purified using the QiAguick gel extraction 581 kit (Qiagen, Valencia, CA, USA), following the manufacturer's protocol. All optional steps were 582 performed, and the final product was eluted in 30 μ l of buffer EB. For samples extracted on the 583 MagNA Pure, amplicons were cleaned using a 1x bead cleanup with Ampure XP beads. Final 584 cleaned amplicons were quantified using the Qubit dsDNA HS Assay kit (Thermo Fisher, 585 Waltham, MA, USA).

586

587 Library preparation and sequencing

588 For each sample, pool 1 and pool 2 amplicons were combined in equimolar concentrations to a 589 total of 0.5 ng in 2.5 µl. Libraries were prepared using the Nextera XT DNA Library Prep Kit 590 (Illumina, San Diego, CA, USA), following manufacturer's instructions, but with reagent volumes 591 halved for each step, for the majority of samples in our dataset. For samples processed in our 592 last sequencing run, several samples had higher Ct values. We therefore chose to process 593 these samples using the standard 1x reagent volumes for the library preparation step. All 594 libraries were purified using Ampure XP beads (Beckman Coulter, Brea, CA, USA), using a 0.6x 595 cleanup, a 1x cleanup, and a final 0.7x cleanup. At each step, beads were washed twice with 596 200-400 μ l of 70% ethanol. The final product was eluted off the beads with 10 μ l of buffer EB. 597 Tagmentation products were quantified with the Qubit dsDNA HS Assay kit (Thermo Fisher, 598 Waltham, MA, USA), and run on a Tapestation with the TapeStation HighSense D5K assay 599 (Agilent, Santa Clara, CA, USA) to determine the average fragment length. All but 8 samples

- and negatives were pooled together in 6 nM libraries and run on 300 bp x 300 bp v3 kits on the
- 601 Illumina MiSeq, with a 1% spike-in of PhiX. The remaining 8 samples
- 602 (MuVs/Washington.USA/1.17/FH77[G], MuVs/Washington.USA/12.17/FH78[G],
- 603 MuVs/Washington.USA/16.17/FH79[G], MuVs/Washington.USA/19.17/FH80[G],
- 604 MuVs/Washington.USA/20.17/FH81[G], MuVs/Washington.USA/20.17/FH82[G],
- 605 MuVs/Washington.USA/29.17/FH83[G], and MuVs/Washington.USA/2.17/FH84[G]) were
- pooled to a 1.2 nM library, and run as a 50 pM library with 2% PhiX on the Illumina iSeq, with a
- 607 151 bp x 151 bp v3 kit.

608 Negative controls

- 609 A negative control (nuclease-free water) was run for each viral RNA extraction, reverse
- 610 transcription reaction, and for each pool for each PCR reaction. These negative controls were
- 611 carried through the library preparation process and sequenced alongside actual samples. Any
- samples whose negative controls from any step in the process resulted in >10x mumps genome
- 613 coverage were re-extracted and sequenced.

614 **Bioinformatic processing of sequencing reads**

- 615 Human reads were removed from raw FASTQ files by mapping to the human reference genome
- 616 GRCH38 with bowtie2 (Langmead and Salzberg, 2012) version 2.3.2 (<u>http://bowtie-</u>
- 617 <u>bio.sourceforge.net/bowtie2/index.shtml</u>). Reads that did not map to the human genome were
- 618 output to separate FASTQ files and used for all subsequent analyses. Illumina data was
- analyzed using the pipeline described in detail at https://github.com/lmoncla/illumina_pipeline.
- Briefly, raw FASTQ files were trimmed using Trimmomatic (Bolger et al., 2014)
- 621 (<u>http://www.usadellab.org/cms/?page=trimmomatic</u>), trimming in sliding windows of 5 base pairs
- and requiring a minimum Q-score of 30. Reads that were trimmed to a length of <100 base
- 623 pairs were discarded. Trimming was performed with the following command: java -jar

624 Trimmomatic-0.36/trimmomatic-0.36.jar SE input.fastg output.fastg SLIDINGWINDOW:5:30 625 MINLEN:100. Trimmed reads were mapped to a consensus sequence from Massachusetts 626 (Genbank accession: MF965301) using bowtie2(Langmead and Salzberg, 2012) version 2.3.2 627 (http://bowtie-bio.sourceforge.net/bowtie2/index.shtml), using the following command: bowtie2 -628 x reference sequence.fasta -U read1.trimmed.fastq,read2.trimmed.fastq -S output.sam --local. 629 We selected this Massachusetts sequence as an initial reference sequence because at the 630 time, it represented one of the only available genomes of a genotype G mumps virus that had 631 been sampled during a US outbreak in 2016. Mapped reads were imported into Geneious 632 (https://www.geneious.com/) for visual inspection and consensus calling. To avoid issues with 633 mapping to an improper reference sequence, we then remapped each sample's trimmed 634 FASTQ files to its own consensus sequence. These bam files were again manually inspected in 635 Geneious, and a final consensus sequence was called, with nucleotide sites with <20x coverage 636 output as an ambiguous nucleotide ("N"). All genomes with >50% Ns were discarded. In total, 637 we generated 140 genomes with at least 80% non-N bases, and 26 genomes with 50-80% non-638 N bases. Our median completeness (percent of bases that are not Ns) across the dataset is 639 90%. All genomes used in these analyses are available at https://github.com/blab/mumps-640 seg/tree/master/data.

641

642 Dataset curation and maximum likelihood divergence tree generation

We downloaded all currently available (as of June 2020), complete mumps genomes from North
America from the NIAID Virus Pathogen Database and Analysis Resource (ViPR) (Pickett et al.,

645 2012) through <u>http://www.viprbrc.org/</u>. We also obtained mumps genomes from British

646 Columbia, Ontario, and Arkansas. We obtained written permission from sequence authors for

- any sequence that had not previously been published on. In total, this dataset includes 437 full
- 648 mumps genomes from North America. Sequences and metadata were cleaned and organized

649 using fauna, a database system that is part of the Nextstrain platform. Sequences were 650 processed using Nextstrain's augur software (Hadfield et al., 2018), and filtered to include only 651 those with at least 8,000 bases and were sampled in North America in 2006 or later. Genomes 652 were aligned with MAFFT (Katoh et al., 2002), and trimmed to the reference sequence 653 (MuV/Gabon/13/2[G], GenBank accession: KM597072). We inferred a maximum likelihood 654 phylogeny using IQTREE (Nguyen et al., 2015) with a GTR nucleotide substitution model, and 655 inferred a molecular clock and temporally-resolved phylogeny using TreeTime (Sagulenko et al., 656 2018). Sequences with an estimated clock rate that deviated from the other sequences by >4657 times the interguartile distance were removed from subsequent analysis. We inferred the root-658 to-tip distance with TempEst version 1.5.1 (Rambaut et al., 2016) with the best fitting root by the 659 heuristic residual mean squared function.

660

661 **Phylogenetic analysis of full North American mumps genomes**

662 Using the same set of genome sequences used for divergence tree estimation, we aligned 663 sequences with MAFFT and inferred time-resolved phylogenies in BEAST version 1.8.4 664 (Drummond et al., 2012). We used a skygrid population size prior with 100 bins, and a skygrid 665 cutoff of 25 years, allowing us to estimate 4 population sizes each year. We used an HKY 666 nucleotide substitution model with 4 gamma rate categories, and a strict clock with a CTMC 667 prior. We used a discrete trait model (Lemey et al., 2009) and estimated migration rates using 668 BSSVS and ancestral states with 27 geographic locations. Here, "state" refers to the inferred 669 ancestral identity of an internal node, where the inferred identity could be any of the 27 670 geographic locations (US states and Canadian provinces) in the dataset. For the prior on non-671 zero rates for BSSVS, we specified an exponential distribution with a mean of 26. As a prior on 672 each pairwise migration rate, we used an exponential distribution with mean 1. All other priors 673 were left at default values. We ran this analysis for 100 million steps, sampling every 10,000,

and removed the first 10% of sampled states as burnin. A maximum clade credibility tree was

summarized with TreeAnnotator, using the mean heights option. All tree plotting was performed

676 with baltic (<u>https://github.com/evogytis/baltic</u>). Input XML files and output results are available at

677 <u>https://github.com/blab/mumps-wa-phylodynamics/tree/master/phylogeography</u>.

678

679 Testing for descendants in divergence trees

680 To determine whether specific groups were more likely to be found at the beginnings of 681 transmission chains than other groups, we developed a statistic to quantify transmission in the 682 tree. Using the tree JSON output from the Nextstrain pipeline (Hadfield et al., 2018), we 683 traversed the tree from root to tip. For each tip that lay on an internal node, i.e., had a branch 684 length of nearly 0 (< 1 x 10^{-16}), we counted the number of descendants. We collapsed very small 685 branches (those with branch lengths less 1 x 10⁻¹⁶) to obtain polytomies. We then classified tips 686 as either having descendants (i.e., the number of descendents was > 0) or not having 687 descendants. Here, we define a "descendant" as a tip that occurs in any downstream portion of 688 the tree, i.e., it falls along the same lineage but to the right of the parent tip. A diagram of what 689 we classify as "descendant tips" is shown in Figure 4a. The probability of having descendants 690 was evaluated as a function of community status, age, and vaccination status with logistic 691 regression as described below.

692

For each Washington tip in the tree, we classified it as either having descendants (coded as a 1) or not having descendants (coded as 0). For each tip, we coded it's corresponding age, vaccination status, and community membership as a predictor variable input into a logistic regression model. We coded these attributes as follows: For community membership, non-Marshallese tips were coded as 0 and Marshallese tips were coded as 1. Age was coded as a single, continuous variable. In our dataset, there were 3 classifications for vaccination status:

699 up-to-date, not up-to-date, and unknown vaccination status. According to the Advisory 700 Committee on Immunization Practices (ACIP) (McLean et al., 2013), individuals aged 5-18 had 701 to have received both recommended doses of mumps-containing vaccine, children aged 15 702 months to 5 years required 1 dose of mumps-containing vaccine, and adults over 18 had to 703 have received at least 1 dose of mumps-containing vaccine to be classified as up-to-date for 704 mumps vaccination. Individuals under 15 months are considered up-to-date without any doses 705 of mumps-containing vaccine. Not up-to-date individuals are those with a known vaccination 706 status who did not qualify under criteria to be classified as up-to-date. Individuals who could not 707 provide documentation regarding their MMR vaccination history were considered to have 708 "unknown" vaccination status. Individuals with "known" vaccination status could either be fully 709 up-to-date, undervaccinated, or unvaccinated. To ensure that we measured the effect of 710 vaccination among individuals who knew their vaccination status, we coded vaccination 711 information using two dummy variables in our logistic regression, one signifying whether 712 vaccination status was known or not, and one indicating whether vaccination was up-to-date or 713 not. We then fit a logistic regression model to this data using the glm package in R 714 (https://www.rdocumentation.org/packages/stats/versions/3.6.2/topics/glm), specifying a 715 binomial model as

716

Pr(having descendants) ~ $\beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3 + \beta_4 x_4$, where x_1 represents 0 or 1 value for member of Marshallese community (Not Marshallese coded as a 0, Marshallese coded as a 1), x_2 represents the numeric value of age, x_3 represents 0 or 1 value for whether vaccination status is unknown (having a known vaccination status coded as a 0, having an unknown vaccination status coded as a 1) and x_4 represents 0 or 1 value for whether vaccination status is up-to-date (up-to-date coded as a 0 and not up-to-date coded as a 1). Under this formulation, an individual with unknown vaccination status would be coded as $x_3=1$, $x_4=0$, an individual who is up-to-date

724	would be coded as $x_3=0$, $x_4=0$, and an individual who is not up-to-date is coded as $x_3=0$, $x_4=1$.
725	This encoding allows us to evaluate the effects of having an unknown vaccination status and a
726	vaccination status that is not up-to-date. Age was normalized such that values fall between 0
727	and 1 by: (x_2 - minimum age in dataset) / (maximum age in dataset - minimum age in dataset).
728	
729	P-values were assigned via a Wald test, and inferred coefficients were exponentiated to return
730	odds ratios. All code used to parse the divergence tree and formulate and fit the regression
731	model are available at https://github.com/blab/mumps-wa-
732	phylodynamics/blob/master/divergence-tree-analyses/Regression-analysis-on-descendants-in-
733	divergence-tree.ipynb.
734	
735	Rarefaction analysis to estimate transmission clusters
736	Using the full set of North American mumps sequences, we designated all non-Washington
737	North American sequences as "background" sequences. We then separated Washington
738	sequences into Marshallese tips (57 total sequences) and non-Marshallese tips (52 total
739	sequences). For this analysis, we excluded the genotype K sequence in our dataset due to its
740	extreme divergence from other viruses sampled in Washington, which were all genotype G. For
741	each group (Marshallese vs. non-Marshallese), we then generated subsampled datasets
742	comprised of a random sample of 1 to n sequences, where n is the number of total sequences
743	available for that group. For each number of sequences, we performed 10 independent
744	subsampling trials. Subsampling was performed without replacement. So, for community
745	members, we generated 10 datasets in which 1 community member sequence was sampled,
746	then 10 datasets in which 2 community members sequences were sampled, etc. up to 10
747	datasets in which all 57 community members sequences were sampled. For each subsampled
748	dataset, we then combined these subsampled datasets with the background North American

749 sequences, and reran the Nextstrain pipeline. For each subsample and trial, we infer 750 geographic transmission history across the tree and enumerate the number of introductions into 751 Washington. Geographic transmission history was inferred using a discrete trait model in 752 TreeTime(Sagulenko et al., 2018). For each number of sequences tested, n, we report the 753 number of trials resulting in that number of inferred introductions, and the mean number of 754 inferred introductions across the 10 trials. Each resulting "cluster" consisted of a set of 755 sequences that are related to one another that descend from a single inferred introduction of 756 mumps into Washington.

757

758 Inference of community transmission dynamics using a structured coalescent model

759 To infer the rates of migration between community and non-community members and to infer 760 ancestral states of Washington internal nodes, we employed a structured coalescent model. 761 Here, "state" refers to the inferred ancestral identity of an internal node, where the identity could 762 be inferred as "Marshallese" or "not Marshallese". The multitype tree model (Vaughan et al., 763 2014) in BEAST 2 v2.6.2 (Bouckaert et al., 2019) infers the effective population sizes of each 764 deme and the migration rates between them. Because the multitype tree model requires that all 765 partitions contain all demes, we could only analyze 4 clades that circulated in Washington State 766 and included both Marshallese and non-Marshallese tips. We generated an XML in BEAUti 767 v2.6.2 with 4 partitions, and linked the clock, site, and migration models. We used a strict, fixed 768 clock, set to 4.17 x 10⁻⁴ substitutions per site year, and used an HKY substitution model with 4 769 gamma-distributed rate categories. This clock rate was set based on the inferred substitutions 770 per site per year from all North American mumps genomes on nextstrain.org/mumps/na. 771 Migration rates were inferred with the prior specified as a truncated exponential distribution with 772 a mean of 1 and a maximum of 50. Effective population sizes were inferred with the prior 773 specified as a truncated exponential distribution with a mean of 1, a minimum value of 0.001.

774 and a maximum value of 10,000. All other priors were left at default values. In order to improve 775 convergence, we employed 3 heated chains using the package CoupledMCMC (Müller and 776 Bouckaert, 2019), where proposals for chains to swap were performed every 100 states. The 777 analysis was run for 100 million steps, with states sampled every 1 million steps. We ran this 778 analysis 3 independent times, and combined log and tree file output from those independent 779 runs using LogCombiner, with the first 10% (1000 states) of each run discarded as burnin. We 780 then summarized these combined output log and tree files. A maximum clade credibility tree 781 was inferred using TreeAnnotator with the mean heights option. To ensure that results were not 782 appreciably altered by the migration rate prior, we also repeated these analyses with migration 783 rates inferred with the prior specified as a truncated exponential distribution with a mean of 10 784 and a maximum of 50.

785

786 Although our complete dataset contains approximately equal numbers of sequences from 787 Marshallese and non-Marshallese cases, the 4 clusters analyzed above are enriched among 788 Marshallese tips. To assess the impact of uneven sampling within these clusters on ancestral 789 state inference, we performed a subsampling analysis. For each cluster, we subsampled down 790 the number of Marshallese tips to be equal to the number of non-Marshallese tips, and reran the 791 analysis as above. While the original analysis used 4 subclades containing both Marshallese 792 and non-Marshallese tips, one of these subclades only has 5 tips. Subsampling this particular 793 subtree would have resulted in a subtree with only 2 tips, thus we excluded this clade from the 794 subsampling analysis. For this sensitivity analysis, the 3 subsampled datasets had the following 795 tip composition: primary outbreak clade: 26 Marshallese and 26 non-Marshallese tips; 10-tip 796 introduction: 3 Marshallese and 3 non-Marshallese tips; 8-tip introduction: 4 Marshallese and 4 797 non-Marshallese tips. We generated 3 randomly subsampled datasets, and for each one ran 3 798 independent chains, with each chain run for 50 million steps, sampling every 500,000. For one

of the subsampled datasets, none of the chains converged after 20 days. In each of the
remaining 2 subsampled datasets, 2 out of 3 chains converged. We combined these converged
chains using LogCombiner, with the first 10% of each run discarded as burn-in. We then
summarized these combined output log and tree files, and inferred a maximum clade credibility
tree using TreeAnnotator with the mean heights option.

804

805 The analysis as described above assumes that each introduction into Washington State is an 806 independent observation of the same structured coalescent process, and that the dataset 807 represents a random sample of the underlying population. Additionally, this approach requires a 808 priori definition of which sequences are part of the same Washington State transmission chain. 809 Finally, the above analysis could only make use of the 4 Washington introductions with both 810 Marshallese and non-Marshallese tips, and excludes other transmission chains. Because of 811 these issues, we supplemented the above approach with an additional analysis using the 812 approximate structured coalescent (Müller et al., 2017) in MASCOT (Müller et al., 2018). Using 813 all of the Washington sequences, we specified three demes: Marshallese in Washington, non-814 Marshallese in Washington, and outside of Washington. To account for any transmission that 815 happened outside of Washington State, the "outside of Washington" deme acted as a "ghost 816 deme" from which we did not use any samples. The effective population size of this "outside of 817 Washington" deme then describes the rate at which lineages between any location outside of 818 Washington share a common ancestor. Including specific samples from outside of Washington 819 would bias the inferred effective population size towards the coalescent rates of the sampled 820 locations, by incorporating local transmission dynamics of other locations. We then estimated 821 migration rates and effective population sizes for all 3 demes, but fixed the migration rates such 822 that the unsampled deme ("outside of Washington") could only act as a source population. This 823 is motivated by not having observed obvious migration out of Washington State in our previous

- analysis here. We ran this analysis for 10 million steps, sampling every 5000, and discarded the
- first 10% of states as burnin.

1045 Acknowledgments

1046 We would like to extend our sincerest thank you to Jiji Jally for her help and input on the project. 1047 Jiji Jally is an advocate for affordable access to healthcare services, supportive services for the 1048 Marshallese community, and works as a translator to assist the community in Washington State. 1049 These insightful discussions were absolutely critical for contextualizing our results. We would 1050 also like to sincerely thank Kelsey Florek for locating and sharing mumps samples from 1051 Wisconsin, Ohio, Missouri, Alabama, and North Carolina, which greatly enhanced the analyses 1052 presented here. We also thank Jeff Joy for graciously sharing mumps genomes from British 1053 Columbia. Finally, we would like to thank the Fred Hutchinson Cancer Research Center 1054 sequencing core for providing excellent sequencing services and Fred Hutch Scientific 1055 Computing Infrastructure. LHM is an Open Philanthropy Project fellow of the Life Sciences 1056 Research Foundation. AB was supported by the National Science Foundation Graduate 1057 Research Fellowship Program under Grant No. DGE-1256082. TB is a Pew Biomedical Scholar 1058 and is supported by NIH R35 GM119774-01. Scientific Computing Infrastructure at Fred Hutch 1059 is supported by NIH ORIP S100D028685.

1060

1061 Author contributions

LHM and AB generated and analyzed data and wrote the manuscript. CD and NRG provided
data and contributed to writing the manuscript. ML, APO, and SL, provided sample and support
for the study. DH provided conceptual input and contributed to the writing of the manuscript.
NFM analyzed data and helped write the manuscript. TB planned the study, supported data
analysis, and wrote the manuscript.

1067

Supplemental Figure 1: Mumps genomes accumulate mutations linearly over time

We inferred a maximum likelihood phylogeny using IQTREE for all available complete mumps genomes of genotype G, sampled from North America between 2006 and 2018. We inferred the root-to-tip distance with TempEst and plot the root to tip divergence vs. sample collection date. Color represents geographic location (either Canadian province or US state), with colors corresponding to those in Figure 2. We infer that mumps genomes accumulate mutations at a rate of 3.75×10^{-4} substitutions per site per year.

Supplemental Figure 2: SH gene sequences are inadequate for fine-scale resolution of mumps tranmission

a. We inferred a maximum likelihood phylogeny using IQTREE for all available complete mumps genomes of genotype G, sampled from North America between 2006 and 2018. Color represents geographic location (either Canadian province or US state), and the x-axis displays divergence in substitutions per site per year. **b.** To compare whether similar results would have been obtained if we had only sequenced the SH gene, we truncated our sequences to include only the coding region for SH and again inferred a maximum likelihood phylogeny using the same procedure as in a. The vast majority of North American mumps sequences are identical and form a single polytomy, suggesting that SH sequencing alone provides limited resolution for inferring geographic spread.

Supplemental Figure 3: Rarefaction results by vaccination status

We repeated the rarefaction analysis shown in Figure 4b for vaccination status. We separated all Washington tips and classified them by vaccination status into up-to-date, not up-to-date, or unknown vaccination status. We then performed a rarefaction analysis and plot the number of inferred Washington clusters (y-axis) as a function of the number of sequences included in the analysis (x-axis). Dark green represents unknown vaccination status, light green represents not up-to-date, and green represents up-to-date. The majority of sequences in our dataset were derived from individuals who were up-to-date for mumps vaccine. Each dot represents the number of trials in which that number of clusters was inferred, and the solid line represents the mean across trials.

Supplemental Figure 4: Inferences are similar under a higher migration rate prior

The results are shown for the exact same analyses displayed in Figure 5, except inferred under a model with a higher migration rate prior (10 instead of 1). **a.** Using the 4 Washington clusters that had a mixture of Marshallese and non-Marshallese cases, we inferred phylogenies using a structured coalescent model. Each group of sequences shared a clock model, migration model, and substitution model, but each topology was inferred separately, allowing us to incorporate information from all 4 clusters into the migration estimation. For each cluster, the maximum clade credibility tree is shown, where the color of each internal node represents the posterior probability that the node is Marshallese. **b.** For each internal node shown in panel **a**, we plot the posterior probability of that node being Marshallese. Across all 4 clusters, almost every internal node is inferred as Marshallese with high probability. **c.** The posterior distribution of the number of "jumps" or transmission events from Marshallese to not Marshallese (light blue) and not Marshallese to Marshallese (dark blue) inferred for the primary outbreak clade.

b

Supplemental Figure 5: Structured coalesent analyses are robust to sampling differences

To ensure that our results were robust to differences in sampling of Marshallese and non-Marshallese tips within the clusters used for this analysis, we subsampled our dataset 3 independent times, and ran 3 independent chains per unique subsampling. In each subsampled dataset, the number of Marshallese tips was randomly subsampled to be equal to the number of non-Marshallese tips in each of the 4 clusters. We then ran each of these subsampled datasets with the exact same model as run with the full dataset. In subsampled datasets 1 and 2, 2 out of 3 chains converged, and results were combined and displayed here. In the 3rd subsampled dataset, none of the 3 chains converged, so those results are not shown. **a.** For each subsampled dataseet, we plot the inferred maximum clade credibility tree from the combined tree outputs from the 2 converged chains. The color of each tip represents whether that sample was derived from a Marshallese or non-Marshallese case, and the color of the internal node represents the posterior probability of that internal node being Marshallese. **b.** For each tree shown in **a**, the posterior probability that each internal node is labelled as Marshallese is shown. The number of the subsampled dataset is shown on the x-axis and the posterior probability is shown on the y-axis.

Supplemental Figure 6: Including all Washington sequences recovers majority of transmission in Marshallese

To ensure that excluding non-Marshallese clusters did not skew our findings, we inferred a single tree using all Washington sequences. We performed a structured coalescent analysis specifying 3 groups: Marshallese, not Marshallese, and not Washington. Each internal node is colored by its most probable group, with its opacity specifying the posterior probability of being in that group (fully opaque being probability = 1, fully transparent being probability = 0).

Supplemental Figure 7: Posterior probabilities of internal node states

a. For the tree shown in Supplemental Figure 6, each internal node is plotted. For each internal node, its color and placement on the x-axis represents its inferred most probable group (Marshallese, Not Marshallese, or Not Washington). The posterior probability of being labelled its most probable group is shown on the y-axis. We recover moderate support for a small number of non-Marshallese internal nodes, while the vast majority of internal nodes remain inferred as Marshallese. **b.** The 95% highest posterior density intervals of the inferred effective population sizes for Marshallese, non-Marshallese, and not Washington demes.

All genomes generated for this analysis are described above. Dates are formatted as Year-month-day. Vaccination status, Ct, and sample collection type are all available for the Washington samples. Genome coverage represents the total proportion of bases in the genome with at least 20x coverage for which we were able to call a base. Sites with <20x coverage were labelled as Ns. Only samples with at least 50% non-N bases were included in the analysis.

Supplemental Table 2: Mumps cases by age group

Age group	Mumps case count	2016-2017 average population in Washington ¹	Rate of cases per 100,000 individuals	Percentage of total cases
0 - 4	34	450,847	7.5	3.8%
5 - 9	104	462,951	22.5	11.7%
10 - 14	198	451,485	43.9	22.3%
15 - 19	214	455,612	47.0	24.1%
20 - 39	256	1,980,004	12.9	28.8%

40 - 64	80	2,348,529.5	3.4	10.0%
65+	2	1,097,571	0.2	0.22%
Unknown	1	NA	NA	0.11%

Supplemental Table 3: Outbreak characteristic and dataset composition

	counts in outbreak (%)	Count in dataset (%)
Up-to-date vaccination	574 (65%)	64 (58%)
Not up-to-date vaccination	86 (9.7%)	13 (12%)
Unknown vaccination status	229 (26%)	33 (30%)
Marshallese	465 (52%)	57 (52%)
Not Marshallese	424 (48%)	53 (48%)
Total	889	110
