Abstract

We study the impact of college openings and teaching modality on county-level COVID-19 cases and
deaths using the information of 745 U.S. colleges. We group the colleges by their teaching modes in the
fall 2020 semester: in-person, online, and hybrid; and employ a logistic model and a gradient boosting
algorithm to estimate the propensity scores for the three groups to adjust the pre-treatment imbalances
of college and county-level covariates. We find that greater enrollments, individual mask policies, and
fewer republican votes in the county are major predictors of adopting online or hybrid modes.
Treatment effects provide evidence that college reopenings, especially with in-person teaching
elements, increase daily new cases and deaths.

COVID-19 Spread in Fall 2020 Semester. medRxiv.

Causal Impacts of Teaching Modality on U.S. COVID-19 Spread in Fall 2020 Semester

1. Introduction

The COVID-19 pandemic and its containment measures have unprecedentedly affected human health

and economic activities (e.g., McKibbin and Fernando, 2020; Atkeson, 2020). Countries across the world

have implemented partial or full business and school closures to mitigate the infection spread

(Panovska-Griffiths et al., 2020; Di Domenico et al., 2020). Many U.S. colleges temporarily closed or

switched to online in the spring semester, and over six out of ten colleges reopened in the fall semester

with an in-person or a combination of in-person and online teaching plans (Gallagher and Palmer, 2020;

College Crisis Initiative, 2020). College students mainly fall in the age cohort of 18 to 29 years, which has

a lower death rate (0.4%) from COVID-19 (Wrighton and Lawrence, 2020), but a greater chance of

socialization than the other age cohorts. Although colleges are following best practices–including

symptom screening, contact tracing, cleaning and disinfecting, and mandatory mask policies–there is a

chance that reopening colleges may spread the virus among faculty and staff serving students, and in

the region around the college (Hubler and Hartocollis, 2020).

Figure (1) and (2) respectively show daily new COVID-19 cases and deaths grouped by college teaching

modality. Both series are shown as percentages of their values on August 10th, 2020 to eliminate the

initial differences and make the figures comparable across groups. Median values are plotted to remove

the influence of extreme observations. Figure 1 suggests that colleges teaching in- person are located in

counties with rapidly increasing COVID-19 cases. Small bumps of cases right before the start dates

indicate reopening-induced testing. In Figure 2, new deaths in counties with colleges teaching in person

are growing faster than hybrid and online groups. Thus, the figures suggest that both COVID- 19 cases

and deaths grow faster in counties where colleges started the fall semester with in-person mode.

Given the substantial risk of infection spread from college campuses to the community, a timely policy

question is whether colleges should continue with in-person classes or switch to online or hybrid mode.

The current study applies a quasi-experimental approach to find the impacts of teaching modality on

infection spread onto the neighboring areas. We combine college and county information to predict the

chance of a college adopting one of the three modes of teaching: in-person, online, and hybrid; and then

estimate the effects of the decision on county COVID-19 outcomes. Results provide evidence that

college reopenings, especially with in-person teaching elements, increase daily new cases and deaths.

Most studies so far have looked into the impact of elementary and secondary school closure, optimal

reopening plan, and teaching strategy (e.g., Di Domenico et al., 2020; Panovska-Griffiths et al., 2020;

Gandolfi, 2020; Cohen et al., 2020; Panovska- Griffiths et al., 2020). Walke, Honein, and Redfield (2020)

discuss the possible issues of U.S. college reopening and the prevention measures required on

campuses. In a study close to ours, Andersen et al. (2020) investigate college openings' association with

cellphone-tracked human mobility and COVID-19 cases in the counties of the campuses. Their

preliminary results (as of September 23rd, 2020) suggest that reopenings with primarily in-person

instruction increased county COVID-19 cases by 0.024 per thousand people, and no significant

differences exist between online and in-person instructional modality. However, their study does not

consider the fact that the choice of reopening and teaching modality is endogenous to observed cases.

We use a matching method derived from multinomial logistic and machine learning to re-weight the

sample based on the college's probability of selecting an instructional mode. This approach also unravels

the predictors of choosing a particular teaching mode. In addition, Andersen et al. (2020) collect start

dates from the fall 2019 semester that may not represent the actual scenario in 2020 because some

college opened early to finish the semester before thanksgiving vacation, whereas some colleges

delayed opening or opened with an online mode waiting for cases to decrease.

2. Method

We are interested in finding the effects of teaching modality on two COVID-19 outcomes: (1) new daily

COVID-19 cases per 100,000 people reported in the county, and (2) new COVID-19 related deaths per

100,000 people in the county. We specify the relationship between college reopening in the fall

semester and the outcome as below,

78
$$Y_{it} = A_0 + \alpha(\text{Fall})_{it} + \beta X_{it} + A_i + e_{it} \tag{1}$$

where, Y_{it} is a COVID-19 outcome, $i = 1, \ldots, N$, and $t = 1, \ldots, T$ respectively indicate colleges and days,

and A_0 is the intercept. Fall is a binary variable that takes value 1 when the college officially reopens for

the fall 2020 semester, and zero for all previous dates. The vector X includes observed daily covariates

such as population mobility, A_i is college fixed effects. Parameters to be estimated include α and β, and

e_{it} stands for the error. Estimating α gives the average difference in Y_{it} between colleges that have

reopened and colleges that have not, because different colleges reopened on different dates.

To measure the average treatment effects (ATE) of teaching modality, let the set {Online, Hybrid, In-

person} denote the options a college can choose from. We re-specify the model as,

95
$$Y_{it} = A_0' + \alpha_1(\text{Online})_{it} + \alpha_2(\text{Hybrid})_{it} + \alpha_3(\text{In-person})_{it} + \beta' X_{it} + A_i' + e_{it}' \tag{2}$$

where, parameters α_1, α_2 and α_3 show the effects of respective treatments on Y_{it}. The parameters in

equation (1) and (2) are technically different, hence the prime ($'$) sign, but have a similar interpretation.

The intercept A_0' represents the overall mean of pre-semester Y_{it}. The causal effects of teaching

modality on COVID-19 outcomes are identified if colleges were homogeneous and were randomly

assigned a teaching mode (Barnow, Cain, and Goldberger, 1981). In practice, the treatment assignment

is not random, because colleges choose the mode of teaching based on their distance education

capacities, observed COVID-19 cases, and many other characteristics. The probability of adopting a

teaching modality, e.g., online, should considerably vary across colleges.

Rosenbaum and Rubin (1983, 1984) discuss propensity score matching (PSM) to adjust the probabilities

for the differences in pre-treatment variables. A propensity score is the conditional probability of

receiving the treatment given the pretreatment variables. In our context, the probabilities of selecting a

teaching mode can be obtained from the following specification.

$$\{Online_i, Hybrid_i, In\text{-}person_i\} = f(College\ features,\ Regional\ features) \qquad (3)$$

The probabilities of treatments generated from equation (3) are used to create weights that adjust the

effects of treatments in estimating equation (2). For example, if a college has a high probability of

choosing online, then hybrid, then in-person, greater weights are assigned on in-person, then hybrid,

followed by online during the estimation (McCaffrey et al., 2013).

The key difference between equation (3) and Rosenbaum–Rubin's matching model is that their model

mainly deals with binary treatments, whereas we have three treatments. Imbens (2000) extends the

concept to multiple treatments, and suggests a multinomial or nested logit for multivalued discrete

response models where the ordering of the response does not matter (see Lopez and Gutman (2017) for

a review). Recent works have also examined the application of machine learning approaches such as

bagging or boosting, random forests, other tree-based methods, and neural networks (McCaffrey,

Ridgeway, and Morral, 2004; Setoguchi et al., 2008; Lee, Lessler and Stuart, 2010; McCaffrey et al.,

2013).

We estimate a multinomial logit model for PSM (equation 3) using cross-sectional data of college and

county features. The predicted probabilities of adopting a teaching mode for each college are then

inverted and used as weights in a panel fixed effects (FE) regression following equation (2). The sources

of variation are colleges for the cross-section, and college times days for the panel. For robustness, we

repeat the task with a gradient booster model instead of multinomial logit. A logit model provides

interpretable coefficient estimates, whereas gradient boosting offers greater predictive accuracy

(Ridgeway et al., 2014; Burgette, Griffin and McCaffrey, 2017). McCaffrey, Ridgeway, and Morral (2004)

and Mc- Caffrey et al. (2013, 2015) discuss the technical details of the two approaches. In simple words,

a gradient booster involves growing decision trees from randomly chosen college and county

characteristics to predict the treatment group, and then repeating the process to explain the residuals

and re-adjust the importance of predictors to achieve the optimal prediction. The algorithm penalizes

complex and large decision trees in order to avoid overfitting (Chen and Guestrin, 2016). The

importance factors on predictors from gradient booster are not as interpretable as coefficients from a

multinomial logit, so we use the gradient booster to predict PSM only, and do not discuss the

importance factors.

3. Data and Descriptive Statistics

We collected characteristics of four-year and two-year undergraduate degree-granting colleges and

universities from the National Center for Education Statistics (2020). Most of the colleges available in

the data are public or private non-profit. Data on teaching modality in the fall 2020 semester come from

the College Crisis Initiative (2020). The College Crisis initiative reports fall reopening plans, which we

categorize into three types: (1) in-person, (2) online, and (3) hybrid. Colleges in the "in-person" group

conduct classes in person with certain exceptions for online delivery and open residence halls; colleges

in the "online" group primarily conduct classes online with some exceptions for lab components and

may have some students on campus; and colleges in the "hybrid" group either switch the teaching mode

on a rolling basis, or offer courses with both in-person and online access. We manually collected the

official start dates of the fall 2020 semester from respective college websites. County characteristics

were extracted from the American Community Survey (2020). Merging all these data eventually gives

745 colleges in bordering states. Alaska and Hawaii were omitted to avoid large heterogeneity in

regional features.

We obtain daily new COVID-19 cases and deaths at the county level from the New York Times (2020).

The impact of teaching modality is assessed on county-level outcomes (and not on the college level)

because students may spread the virus to non-students and immunocompromised people in the

community, which is a pressing policy concern. We also merged the data with individual mask policies in

county and state from HealthData.gov (2020). Finally, information on county-level shares of republican

votes in Presidential Election 2016 is included from McGovern et al. (2017) to take residents' perception

of COVID-19 risk into account (e.g., Tyson, 2020).

Table (1) provides variable descriptions and sources, and Tables (2) and (3) respectively present

summary statistics of variables used in PSM and panel FE. For the panel regression, we chose August 10

as the starting point of data to spare two weeks before the start date of the fall semester. Maximum

colleges (212 out of 745 in our sample) started the semester on August 24th. September 19th, 2020 was

chosen as the endpoint based on data availability. The panel regression use college fixed effects, and

controls for the percentage of county population stayed home daily, collected from the Bureau of

Transportation Statistics (2020). Omitting stay-home makes the effects of a teaching mode on COVID-19

outcomes biased, because COVID-19 outcomes may increase if fewer people stay home regardless of

campus reopening or teaching modality.

A required condition for estimating treatment effects is distributional similarities of pre-treatment

covariates across the treatment groups McCaffrey et al. (2013). Table (2) and table (4) indicate

considerable variation across treatment groups. The mean different t-tests are significant especially

when variables are compared between online and in-person group. The difference justifies the use of

PSM in our analysis. In fact, comparing propensity scores across treatment groups is equivalent to

comparing the pre-treatment covariates, which is done in the next section.

4.   Results

To calculate the probability of choosing each teaching mode and re-adjust the weights, we use a

multinomial logistic regression. The results in table (5) shows that colleges that chose online teaching

mode over in-person have greater enrollment, endowment per student, and are public in nature.

Online-teaching colleges are located in a county that has more population, on-going mask ordinance,

and fewer republican votes. From hybrid and in-person comparison in table (5) column (2), hybrid-

adopting colleges have more enrollment, a lower cost of attendance, fewer students per faculty and are

located in a county with fewer republican votes. To summarize, greater enrollment, fewer republican

supporters in the county, and prevailing individual mask ordinance are common predictors of adopting

online or hybrid teaching modality over in-person.

We use the multinomial logit model to calculate the propensity scores for each college. The scores need

to be sufficiently similar across groups for causal estimation. Figure (3) compares the distributions of the

propensity scores using box plots. The distributions are overlapping–an essential feature for causal

estimation (McCaffrey et al., 2013). We invert the scores and use them as weights to adjust the

difference of college and county characteristics across treatment groups. The maximum Kolmogorov-

Smirnov (KS) statistic of distributional equality is 0.33 for the unweighted sample and 0.12 for the

weighted sample, with p-values zero and 0.059, respectively. Therefore, we reject the null hypothesis of

distributional equality for the unweighted sample, but fail to reject the null for the weighted sample.

That is, we use PSM to create a weighted sample such that any teaching mode is equally likely to be

chosen by a college. We now utilize the weighted sample to estimate the causal effects of teaching

modality on COVID-19 cases and deaths.

Tables (6) and (7) present the results from the panel fixed effects regression. The dependent variables

(1) daily new COVID-19 cases per 100,000 people and (2) daily new COVID-19 deaths per 100,000 people

do not have autocorrelation. The adjusted t statistics from Levin, Lin, and Chu (2002) unit-root tests are -

59.56 and -71.89 respectively, both significant at 0.01%.

Overall, daily new COVID-19 cases increased in the fall 2020 semester, by about 1.87 cases per 100,000

population. Cases increased the most where colleges adopted an in-person teaching mode, followed by

hybrid, compared to the pre-semester benchmark (table 6 column 2). Online dummy is statistically

insignificant– showing no difference in cases between online teaching and pre-semester situation.

However, effects on COVID-19 cases become similar for online (+1.8) and hybrid (+1.6) modes when we

control for the endogeneity (table 6 column 3). Most importantly, counties where colleges reopened

with an in-person mode experienced a statistically significant rise of 2.5 new cases. The results remain

robust when we estimate the propensity scores with Gradient Booster (table 6 column 4). Table (7) also

show a positive effect of campus reopening on daily new COVID- 19 deaths–about 0.04 per 100,000

population. The mean effect is disentangled by teaching modes: in-person teaching mode raises the pre-

semester death rate by 0.049, followed by hybrid (0.048), and online (0.035) (table 7 column 2). Online

dummy becomes insignificant when PSM weights from multinomial logit are used, but the magnitude of

the coefficient is similar to that of the hybrid dummy when weighted by gradient booster propensity

scores. The effect of in-person teaching modes remains statistically significant and greater than other

modes' in all specifications.

We find a mixed result on the effects of online and hybrid modes–none is consistently greater than the

other. One explanation is that students might choose online when offered a combination (hybrid) of

208 online and in-person. Finally, a percent increase in the county population who stayed home decreases

209 new COVID-19 cases by about 0.7, and new deaths by 0.035 per 100,000 population. The effect is

210 consistent across the models.

212   5. Policy Implications

213 Our findings have several implications for higher education and health policy. First, results from the

214 multinomial logit suggest that colleges with smaller endowments per student are less likely to choose

215 online over in-person teaching mode. Moreover, the treatment effects show adopting an in-person

216 mode instead of an online mode may increase COVID-19 cases and deaths. Therefore, colleges with

217 small endowments need special policy attention to combat a disease-induced pandemic.

218 Second, campus reopening has a positive impact on COVID-19 cases and deaths that is primarily driven

219 by in-person teaching modes, and cannot be avoided completely even when colleges choose online.

220 However, the damage can be partially mitigated with an initiative from the colleges by increasing

221 distance education elements in classes.

222 Third, we found a direct negative association between the percentage of county residents staying home

223 and COVID-19 spread. Policies aimed at individual mask use might have an indirect negative effect on

224 COVID-19 as well. Given other attributes, counties that start mandatory mask use in public places are

225 likely to nudge college administration towards online or hybrid classes, which in turn reduce the virus

226 spread in the community.

227 Finally, counties with more republican votes in Presidential Election 2016 are less likely to choose online

228 or hybrid modes over in-person, ceteris paribus. The finding indicates that political affiliation might play

229 a role in the containment of COVID-19.

Household income	USD	ACS (2020)	Median real household income in the past 12 months (2018)
Republican votes	Percentage	McGovern et al. (2017)	Percentage of votes for the Republican Party at the county level in Presidential election 2016
Mask ordinance	Binary	HealthData.gov (2020)	The county has an ongoing mandatory mask policy for individuals in public places
Cases in spring	Count	NYTimes (2020)	Total COVID-19 cases in the county by May 15, 2020
Deaths in spring	Count	NYTimes (2020)	Total COVID-19 deaths in the county by May 15, 2020
Time-varying variables used in panel fixed-effects regression			
New cases	Numeric	NYTimes (2020)	Daily new COVID-19 cases per 100,000 population in the county
New deaths	Numeric	NYTimes (2020)	Daily new COVID-19 deaths per 100,000 population in the county
Fall semester	Binary	College websites	Takes 1 when the college officially started fall semeseter classes
Online	Binary	CCI (2020)	Takes 1 when the college starts classes primarily online for fall 2020, zero otherwise
Hybrid	Binary	CCI (2020)	Takes 1 when the college starts a combination of online and in-person modes, zero otherwise
In-person	Binary	CCI (2020)	Takes 1 when the college holds classes primarily in person for fall 2020, zero otherwise
% stayed home	Percentage	BTS (2020)	Percentage of county population that did not go outside home for longer than 10 minutes
Time	Day		Calendar days from August 10, 2020 to September 19, 2020

361 Table 2. Summary statistics of variables used in matching

Variable	(1) Online	(2) Hybrid	(3) In-person	(4) Overall
College features				
Enrollment	8,088	5,715	4,438	6,109
	(9,959)	(7,439)	(7,107)	(8,492)
Cost of attendance	45,768	46,196	43,010	44,827
	(21,017)	(19347)	(16,237)	(18,930)
Endowment per student	64,685	77,841	51,170	62,836
	(328,815)	(337,832)	(366,540)	(345,508)
Student faculty ratio	26.65	22.40	24.75	24.86
	(16.50)	(12.15)	(19.94)	(17.05)
Public	0.35	0.25	0.23	0.28
	(0.48)	(0.43)	(0.42)	(0.45)
County features				
Total population	1,377,642	560,900	392,161	799,380
	(2,488,077)	(841,262)	(781,868)	(1,702,115)
Black population (%)	15.11	13.20	11.48	13.26
	(15.99)	(14.64)	(13.49)	(14.81)
