The impact of COVID-19 employment shocks on suicide and safety net use: An early-stage investigation[*]

Michihito Ando[†]   Masato Furuichi[‡]

May 6, 2021

Abstract

This paper examines whether the COVID-19-induced employment shocks have increased suicides and safety net use in the second and third quarters of 2020. We exploit plausibly exogenous regional variation in the magnitude of the employment shocks in Japan and adopt a difference-in-differences research design to identify the employment-shock impact. Our preferred point estimates suggest that a one-percentage-point increase in the unemployment rate in the second quarter of 2020 resulted in, approximately, an additional 0.39 suicides, 89 and 82 recipients of two temporary loan programs, 28 recipients of the Housing Security Benefit, and 11 recipients of Public Assistance per 100,000 population per month. A simple calculation based on these estimates suggests that if a region experienced a one-percentage-point increase in the unemployment rate caused by the COVID-19 crisis in the second quarter of 2020, which is roughly equivalent to the third-highest regional employment shock, this could have led to 30.3%, 40.4%, and 25.2% increases in the total, female, and male suicide rates respectively in July 2020 compared with July 2019.

1 Introduction

The COVID-19 pandemic has caused serious infections and deaths around the world, and it is becoming clearer that its economic and social consequences are also tremendous. The COVID-19 pandemic and subsequent social-distancing policies have caused a sharp contraction of economic and social activities. National governments around the world have been trying to mitigate socio-economic damages by introducing new emergency cash benefits and expanding existing safety net programs. There are daily news reports of job loss, poverty, mental disorders, and even suicides that have been directly or indirectly induced by the COVID-19 crisis. Numerous social-science studies of the impact of the COVID-19 crisis have also been published on a daily basis.

However, it is still not well understood how the COVID-19 economic shocks, such as a sharp increase in unemployment, have affected society. Previous social-science studies have tended to focus on how the COVID-19 crisis *as a whole*, including social-distancing policies, has affected economic and social outcomes, but fewer studies have directly examined the effects of COVID-19-induced *employment shocks* on social outcomes such as mental and financial distress.

In this paper, we provide an early-stage analysis on how the COVID-19-induced employment shocks affect suicide and financial distress in Japan. We exploit an increase in the regional unemployment rate as an indicator of the economic shocks because unemployment can directly harm the well-being of workers and their families. We focus on suicide and safety net use as social outcomes because the former can be interpreted as a devastating consequence of deteriorated well-being and the latter are administrative indices that reflect the number of people or households that suffer from distressed living and financial conditions.

As a research design, we exploit a considerable regional variation in the magnitude of the COVID-19-induced increase in unemployment: regional (i.e, prefecture-level) employment shocks were larger in metropolitan areas and regions with popular sightseeing spots where a greater portion of employed people work in the service industry. Then we adopt an even-study difference-in-differences (DID) research design and examine how the regional employment shocks caused by COVID-19 are correlated with the regional trends of suicide rates and safety net participation before and during the crisis. As for safety net programs, we examine five programs in Japan's three-tier safety net system addressing unemployment and poverty: unemployment benefits (first tier), two temporary loans and temporary housing benefits (second tier), and a public assistance program (third tier).

Our preferred point estimate suggest that a one-percentage-point increase in the unemployment rate in the second quarter (i.e., April to June) of 2020 resulted in, approximately, an additional 0.393 suicides in the subsequent month. This effect size is not negligible given that the suicides rate was 1.297 in July 2019 (based on

the estimated days of death), implying a 30.3% increase in the suicide rate. The counterpart estimates and the rates of increase for female and male suicide rates are 0.325 and 40.4% and 0.488 and 25.2% respectively.

Our results also imply that the same one-percentage-point increase in the regional unemployment rate led to no statistically significant increase in unemployment benefits, but resulted in an additional 89 and 82 recipients for two temporary loan programs, 28 recipients for temporary Housing Security Benefit, and 11 recipients for Public Assistance per 100,000 population per month. There having been no effect on the first-tier unemployment benefit appears incomprehensible, but our further investigation suggests that this may be explained by the fact that our baseline treatment variable with the unemployment rate is closely related to the COVID-19-induced regional employment shocks for contingent workers who were not entitled to receive unemployment benefits.

The contributions of our paper are three-fold. First, we provide early-stage plausible evidence of the impact of the COVID-19-induced employment shocks on mental and financial distress such as suicide and safety net use, which has rarely been studied so far except for some surveys [1]. Note that the impact of the COVID-19 pandemic on socio-economic outcomes including unemployment and safety net use has been extensively studied [2, 3, 4, 5, 6]. There are also several epidemiological studies that investigate suicide under the COVID-19 shocks [7, 8, 9, 10, 11, 12, 13]. Some studies also point out that the rise in unemployment caused by the COVID-19 pandemic is expected to lead to an increase in the suicide rate [14, 15]. One study examines the possible long-run impacts of COVID-19 economic consequences on various socio-economic outcomes from a historical perspective [16]. None of these studies, however, directly investigate the effects of COVID-19-induced regional employment shocks on suicide and other socio-economic outcomes as we do.

Second, from a more general viewpoint, our study also contributes to the literature on the impact of unemployment on suicide. The effect of unemployment on suicide has been extensively studied in social sciences [17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27] and public health (see a systematic review [28]) and many studies have shown that increases in unemployment are associated with a rise in the suicide rate. For example, Ruhm [17] shows that a one-percentage-point increase in the state unemployment rate was associated with an approximate 1.3% increase in the suicide rate in the US and some studies reviewed in Franquiho et al. [28] provide counterpart estimates with a range of 0.79-4.5% increases. These estimates in the previous studies are much lower than our counterpart estimated effect size of 30.3%, but one caveat is that our estimate represents the largest monthly, not yearly as in most studies, effect in the second and third quarters of 2020.

Third, our study is also related to the literature on the impact of unemployment on poverty and safety net use. Some studies examine the impact of unemployment-

rate fluctuation on use of safety net programs such as unemployment insurance benefits and means-tested programs before the COVID-19 crisis [29, 30, 31]. Our findings add new evidence to the literature by estimating and comparing the impact of unemployment on the use of multi-tier safety net programs.

The rest of the paper is organized as follows. Section 2 provides background information about the COVID-19 socio-economic crisis in Japan with time-series graphs. Section 3 describes our research design, empirical model, and data. In Section 4 we present baseline estimation results and in Section 5 we also provide the results of robustness checks and alternative estimations with a different employment-shock variable. Section 6 concludes.

2 Background

Japan has suffered from economic and social difficulties despite its relative success in mitigating COVID-19 infection spread without imposing a strict lockdown policy. As panels (a) and (b) in Figure 1 shows, in Japan, the COVID-19 employment shocks emerged as sharp drops in the employment rate and labor force participation (LFP) rate since April 2020, while the indices of the unemployment rate and the jobs-to-applicants ratio (i.e., the ratio of job offers to job applicants) gradually deteriorated.

In turn, panels (c) and (d) in Figure 1 suggest that suicide rates have been increasing since July 2020. It is not clear from this graph to what degree the COVID-19 crisis has led to the increase in suicides, but some specialists and reports in the mass media have asserted that the sharp deterioration in employment in the first few months of the COVID-19 crisis may have resulted in the slightly lagged increase in suicides [32, 33]. In appendix A, we present the numbers of suicides in 2019 and 2020 by sex, age and occupation and these data show that the increase in suicides from 2019 and 2020 stands out in both employed and non-employed women within all age cohorts and young employed men aged 20-29.

Furthermore, Figure 1 also shows that the use of several social safety net programs also increased in the COVID-19 crisis. Panel (e) shows that the number of unemployment benefits under the Unemployment Insurance, which is sometimes called the *first-tier* safety net for unemployment in Japan, clearly increased since July 2020. Panel (f) also shows that the numbers of accepted applications for public temporary loan programs (Emergency Small Amount Funds and General Support Funds) and temporary housing allowance called Housing Security Benefit, which are considered to be *second-tier* safety nets, also sharply increased from April 2020 after the relaxation of requirements. On the other hand, panel (g) shows that the number of recipients of the Public Assistance program, which can be regarded as a *third-tier* safety net and is often called a "last resort", continued to slightly decrease even during the COVID-19 crisis. But when we examine the year-on-year

Figure 1: Monthly trends of employment-related variables, suicides and safety-net programs

Notes: A vertical line in January 2020 indicates the beginning of the COVID-19 crisis in Japan. "Year-on-year" means year-on-year difference. Suicides in panels (c) and (d) are counted based on the estimated dates of death. In panel (f), "Emergency Small Amount Funds" and "General Support Funds" are two public temporary loan programs and "Housing Security Benefit" is a temporary housing allowance program. In panel (h), "the elderly" indicates a household with only persons aged 65 or over (and unmarried persons under the age of 18), "single mothers" means households with unmarried women and their children under the age of 18, "the disabled" or "the sick" are households the heads of which are persons with a disability or sickness respectively. See Section 3 for more details about these data.
Sources: See Table B.1 in Appendix B.

numbers of recipient households by household types in panel (h), the number of "others", which should include low-income households that are sensitive to employ-

ment shocks, clearly started increasing in April 2020.

3 Research design and data

3.1 Regional employment shocks

Exploiting the sudden and plausibly exogenous regional variation in the COVID-19-induced employment shocks at the prefecture level, we adopt an event-study DID strategy to investigate the effect of the COVID-19 employment shocks on suicide and safety net use. Japanese prefectures, such as Tokyo, Kyoto, and Hokkaido, are comparable to states in the U.S. and provinces in Canada and some European countries, and number 47 in total.

We define the COVID-19-induced employment shock as the following de-trended increase in the regional unemployment rate in the second quarter (i.e. April to June) in 2020:

$$EmpShock_i = [(X_{i,2020Q2} - X_{i,2019Q2}) - (X_{i,2019Q4} - X_{i,2018Q4})], \qquad (1)$$

where i indicates prefecture, X is the unemployment rate, and $Q2$ and $Q4$ are the second and fourth quarters respectively. The first term in equation (1) is a year-on-year difference in the unemployment rate in the second quarter of 2020, which consists of a COVID-19-induced employment shock and a prefecture-specific year trend. The second term is a corresponding year-on-year difference in the fourth quarter of 2019, which should reflect a prefecture-specific year trend just before the COVID-19 crisis. Assuming that the prefecture-specific year trends are similar just before and after the COVID-19 crisis, the difference between these two terms is thus expected to capture only the COVID-19-induced employment shock.

We assume that a major, though not exclusive, causal pathway of the COVID-19 impact on suicide and safety net use at the regional level is via the employment shock $EmpShock_i$. This assumption should be plausible for the following three reasons. First, some surveys show that mental distress under the COVID-19 crisis in Japan is closely related to employment status and low income [9, 34]. Second, all the safety net programs examined in this paper are only available to people who are unemployed or in severe economic circumstances. Third, although non-economic shocks such as COVID-19 infections and social distancing measures might have directly affected suicide, their magnitudes and regional variations are expected to be small given the facts that, in the second quarter of 2020, Japan's infection rate was among the lowest in developed countries and major social distancing measures had been implemented at the national level rather than the regional level: cumulative confirmed COVID-19 deaths per million people at the end of June 2020 are 596.28 for the U.K., 385.50 for the U.S., 299.23 for the EU, and 7.68 for Japan according

to Our World in Data and Japan's first Declaration of a State of Emergency was announced on April 7 for seven high-risk prefectures, but this Declaration was soon extended to the entire country on April 16 and was gradually lifted in multiple phases from May 14th to 25th.

Note that what we use is the prefecture-level estimates of the unemployment rate provided in the Labour Force Survey. The prefecture-level estimates are estimated by the Statistics Bureau. The Bureau states that some imprecision is expected in these estimates, but we treat the estimated values as true values and do not consider their statistical uncertainty in our statistical analysis due to data limitation.

3.2 Outcome variables

For outcome variables, we focus on total, female, and male suicide rates and five safety net programs used in Figure 1. See also Ando et al. [35] for more details about Japan's fiscal measures and safety net programs addressing COVID-19 in the first six months of the COVID-19 crisis.

Suicide rates Our primary outcome of interest is the suicide rate, which is the number of suicides per 100,000 population. We investigate the monthly panel data of three suicide-rate variables: total suicide rate, female suicide rate, and male suicide rate. We use the prefecture-level data between January 2019 and September 2020 and the number of suicides is aggregated based on the dates and places of suicide. Suicide statistics are originally provided as police statistics and aggregated and arranged by the Ministry of Health, Labour, and Welfare (MHLW) as the Statistics of Suicide. (*Jisatsu no Tokei*).

Unemployment benefits The first outcome of a safety net program examined is the number of unemployment benefit recipients per 100,000 population under the Unemployment Insurance. The Unemployment Insurance is unarguably the first-tier safety net program for the unemployed in most developed countries, but there are some caveats about the Japanese unemployment insurance system. First of all, the coverage rate of the unemployment benefits among unemployed was less than 30% in Japan in the early 2010s and it is lower than other developed countries even after taking into account institutional differences [36]. Second, the COVID-19-induced employment shocks are more concentrated on part-time or contingent workers [6] and contingent workers are often not eligible for unemployment benefits. Hence there is a possibility that the Unemployment Insurance did not work well as a social safety net against the COVID-19 employment shocks [37].

Temporary loan programs The second and third outcomes of safety net programs are the numbers of accepted applications per 100,000 population for two types

of interest-free and guarantor-free emergency temporary loan programs: Emergency Small Amount Funds for those who urgently need cash (up to 200,000 JYP or about 1,900 USD) and General Support Funds for those who need cash for a certain period (up to 150,000-200,000 JYP per month). They are both existing means-tested temporary loan programs which can be utilized as second-tier safety net programs before applying for Public Assistance. They were rarely used before the COVID-19 crisis (see Figure 1). However, their requirements have also been relaxed since March 2020 and the number of loan recipients has increased dramatically. We use the monthly data between January 2019 and September 2020, but due to the limited data availability we do not have the data for February and March 2020: Statistics in these two months were missing from the original data provided by the government. In addition, the monthly-level data aggregation from April to July 2020 is slightly irregular, although it should not cause serious estimation bias. More concretely, the number of loan decisions between April and July 2020 in the statistics provided by the central government is aggregated as follows: April data is based on the numbers from 25th March to 2nd May, May data is from 3rd May to 30th May, June data is from 31st May to 27th June, July data is from 28th June to 1st August, August data is from 2nd August to 29th August, and September data is from 30th August to 3rd October.

Housing Security Benefit The fourth safety net program outcome is the number of accepted applications per 100,000 population for the Housing Security Benefit, which is an existing scheme of short-term (i.e. three to nine months) housing allowance, which is also a second-tier safety net program in Japan. This benefit scheme, originally intended only for those who have lost their jobs, was rarely used before the COVID crisis as shown in Figure 1. But since April 2020, its eligibility has been extended to those who have not lost their jobs but have still experienced a large income reduction, resulting in a considerable increase in the number of households receiving the benefits. Because of the limited data availability, we can use only January, February, and March 2019 in the pre-COVID-19 period.

Public Assistance The fifth and sixth variables of safety net programs are the per-capita numbers of Public Assistance recipients and recipient households. The Public Assistance program in Japan, the third-tier safety net, is considered to be the "final safety net" or "last resort," and the prerequisites for application are in general strict, such as having no savings and no assets. We can use only total recipient and total recipient household numbers for monthly prefecture-level data.

3.3 Empirical model

The baseline model specification takes the following event-study specification with time-varying DID coefficients:

$$Y_{it} = \pi_i + \theta_t + \phi_i t + \sum_{\tau \neq 2020Jan} \beta_\tau EmpShock_i \times 1[t = \tau] + \varepsilon_{it}, \qquad (2)$$

where Y_{it} is the outcome variable such as a suicide rate for prefecture i at time t, π_i and θ_t are prefecture and month fixed effects, respectively, $\phi_i t$ is an individual (i.e. prefecture) linear trend, $Empshock_i$ is a continuous treatment variable of the COVID-19 employment shock defined as in (1), $1[t = \tau]$ is a dummy variable that takes the value of one if $t = \tau$ and zero otherwise, and ε_{it} is an error term.

The coefficients of interest are the time-varying coefficients β_τ, which capture the correlation between $EmpShock_i$ and the outcome trend from January 2020 to time τ. When time τ is before January 2020, β_τ can be interpreted as a placebo estimate that is expected to be zero if no confounding trends existed before the COVID-19 crisis. When month τ is after January 2020, β_τ can be seen as the average impact of $EmpShock_i$ given that the placebo estimates are around zero and the assumption of no differential trends in the COVID-19 period is plausible.

In the baseline regression analysis, we use the weighted least square (WLS) estimation method in which prefecture-level population sizes are used as weights. With this WLS model, the heterogeneous effect of the employment shock on an outcome for a larger prefecture is more highly weighted in a DID estimator. In the section of robustness checks, we also use the ordinary least square (OLS) estimation method because it is not clear whether a WLS estimator is more appropriate than an OLS estimator as an estimator of a population average effect when effect heterogeneity exists [38].

Furthermore, for the outcomes of the two temporary loan programs and the Housing Security Benefit, we do not include an individual linear trend $\phi_i t$ in the model (2) because the levels of these outcomes are negligible in the pre-COVID-crisis period compared with the COVID-crisis period (see Figure 1). As robustness checks, we also provide estimation results of all the other outcomes with the estimation model that does not control for the individual linear trends.

3.4 Data exploration

Table 1 shows the summary descriptive statistics of our treatment and outcome variables. We use the panel data of 47 prefectures from January 2019 to September 2020 (21 months) and the full sample size is 987. Because the employment-shock variable defined in equation (1) is a time-invariant and cross-sectional variable, we have 47 observations. The outcome variables such as suicide rates, unemployment

benefits, and Public Assistance recipients include 21-months of data (from January 2019 to September 2020) while the variables of Emergency Small Amount Funds, General Support Funds, and Housing Security Benefit are more restricted due to data limitations as already explained.

Table 1: Summary Descriptive Statistics

Statistic	N	Mean	St. Dev.	Min	Max
Employment shock	47	0.25	0.42	−0.77	1.23
Suicide rate (total)	987	1.32	0.38	0.18	3.27
Suicide rate (female)	987	0.76	0.34	0.00	2.14
Suicide rate (male)	987	1.92	0.62	0.00	4.69
Unemployment benefits (total)	987	335.96	64.61	214.50	526.63
Unemployment benefits (female)	987	398.60	82.19	238.53	607.71
Unemployment benefits (male)	987	284.53	55.34	187.25	454.55
Emergency S.A. Funds, accepted	893	28.51	55.85	0.00	567.45
General Support Funds, accepted	893	14.90	36.93	0.00	426.29
Housing Security Benefit, accepted	423	6.13	9.49	0.00	81.26
Public Assistance recipients	987	1,393.91	661.48	340.76	3,190.90
Public Assistance recipient households	987	1,105.99	514.02	297.24	2,501.60

Notes: The employment shock is a cross-section variable calculated based on equation (1). All the other variables are calculated per 100,000 population. For the definition of each variable, see Table B.1 in Appendix B. Outcome variables such as suicide rates, unemployment benefits, and Public Assitance recipients are 21-months data (from January 2019 to September 2020) while the variables of Emergency Small Amount Funds, General Support Funds, and Housing Security Benefit are more restricted due to data limitation. Sources: See Table B.1 in Appendix B

Figure 2 shows the regional variation of the employment shock measured as equation (1) (panel (a)) and correlations of this employment shock and changes in total, female, and male suicide rates in July 2020 from the average of the three corresponding suicide rates in 2017-2019 (panel (b)-(d)). We use the monthly suicide rates in July because our employment-shock variable is calculated as a shock in the second quarter (i.e. April to June) 2020.

Panel (a) shows that the most affected prefectures are Okinawa, Kanagawa, and Osaka and their employment shocks are more than one percentage point. Panel (a) also suggests that these employment shocks are larger in metropolitan areas (Kanagawa, Osaka, Nara, Tokyo, Hyogo, Saitama, Chiba, Kyoto) and prefectures with popular sightseeing spots (Okinawa and Hokkaido). Panel (b)-(d) present some positive correlations between the employment shock and the suicide rates.

Figure 2: Changes in the unemployment rate and suicide rates

Notes: In all four graphs, the X axis is the size of an employment shock defined as in (1). The Y axis in panels (b)-(d) is a change in the suicide rate in July 2020 from the average of the three corresponding suicide rates in 2017-2019. The size of each circle is based on the population size of each prefecture. The dashed line is the fitted linear regression line based on the Ordinary Least Square (OLS) method.

Sources: See Table B.1 in Appendix B

4 Results

4.1 Suicide rates

Figure 3 shows the estimation results for the suicide rates based on (2) using WLS. First, DID estimates in the pre-COVID-19 period are more or less zero, implying that there is no clear statistically significant correlation between the employment shock and all the outcome trends before January 2020. Second, when it comes to the post-COVID-19 estimates after January 2020, the estimates for total, female, and male suicide rates are positive from May to July and the lower limits of the 90% confidence intervals are often above or near zero. The sizes of the estimates in July

2020 suggest that the one-percentage-point increase in the unemployment rate in the second quarter of 2020 led to 0.393, 0.325, and 0.458-point increases (or 30.3%, 40.4%, and 25.2% increases from July 2019) in the total, female, and male suicide rates respectively. Note that the total, female, and male suicide rates in July 2019 were 1.297, 0.805, and 1.815 respectively. In August and September, estimates are not significantly different from zero, implying that suicides in this period are not directly related to the second-quarter employment shock in 2020.

Overall, the DID estimates suggest that the COVID-19-induced employment shocks have led to increases in both female and male suicides. The magnitudes of the estimated impacts are not small. Simple calculation based on the estimate suggests that if a region with a population of 10 millions experienced a one-percentage point increase in the unemployment rate caused by the COVID-19 crisis in the second quarter of 2020, which is roughly equivalent to the third-highest employment shock on Osaka (see Figure 1), this could have led to an additional 39.3 suicides in July 2020. Another back-of-envelop calculation suggests that, if Japan experienced the same one-percentage-point employment shock and the homogeneous nationwide employment-shock effect of a 0.393 point increase, this could have led to an additional 495 suicides (i.e., 126 millions, population estimate in July 2020, times 0.393) when the counterpart monthly suicide number is 1,637 in the previous year.

4.2   Safety net use

Figure 4 provides estimation results for safety net participation. To begin with, in the first row panels (a) and (b) correspond to estimates for the first-tier safety net program, that is Unemployment Insurance. DID estimates for the number of unemployment benefits for total, female, and male unemployed are unstable and not significantly different from zero in the COVID-19 crisis period. This surprising result may be explained by the fact that the unemployment-benefit coverage rate is low in Japan and that COVID-19-induced employment shocks are more concentrated on contingent workers who are often not eligible for unemployment benefits (Section 3.2).

The second row, panels (c) and (d), of Figure 4 provides estimates for the second-tier safety net programs: the two temporary loan programs and the Housing Security Benefit. They are mostly significantly different from zero in the COVID-crisis period, in particular in June and July, suggesting the positive effects of the second-quarter employment shocks on these programs. Note that the numbers of accepted applications for these programs are discontinuously smaller in the pre-COVID-19 period, so the pre-COVID-19 estimates are negligible and we cannot evaluate differential trends in these outcomes.

The third row, panels (e) and (f), of Figure 4 provide estimation results for the numbers of persons and households that receive Public Assistance, the third-tier

Figure 3: DID estimates for suicide rates

(a) Total suicide rate

(b) Female suicide rate

(c) Male suicide rate

Notes: Each plot indicates a point estimate and a vertical line indicates a 90% confidence interval. The treatment variable is the COVID-19-induced employment shock, which is calculated as equation (1). Estimates are obtained based on equation (2) with WLS estimation weighted by prefecture population size. Because equation (2) incorporates individual (i.e. prefecture) linear trends, estimates can be obtained from February 2019.

safety net. Results show that estimates in the COVID-19 period are significantly different from zero while estimates in the pre-COVID-19 period are mostly not. While the estimates for the temporary loan programs and the Housing Security Benefit peaked in June or July 2020, the estimates for Public Assistance continued

Figure 4: DID estimates for safety net programs

Notes: Each plot indicates a point estimate and a vertical line indicates a 90% confidence interval. The treatment variable is the COVID-19-induced employment shock, which is calculated as equation (1). Estimates are obtained based on equation (2) with WLS estimation weighted by prefecture population size. Because equation (2) incorporates individual (i.e. prefecture) linear trends for panels (a),(b), (e) and (f), estimates can be obtained from February 2019. For the outcomes of accepted applications for the temporary loans and the Housing Security Benefit (panels (c) and (d)), individual linear trends are not introduced due to discontinuously smaller outcome values in the pre-COVID-19 period. For the outcome of the accepted applications for the Housing Security Benefit, the reference year is March 2019 instead of January 2020 due to the lack of data. But this should not affect estimation results because the number of accepted applications for the Housing Security Benefit is negligible before the COVID-19 crisis.

to increase through the third quarter of 2020.

The point estimates for the temporary loan programs and Housing Security Benefit suggest that a one-percentage-point increase in the unemployment rate in the second quarter of 2020 resulted in an additional 88.8 accepted applications for Emergency Small Amount Funds in June, an additional 82.4 accepted applications for General Support Funds in July, and an additional 27.6 accepted applications for the Housing Security Benefit in June (all per 100,000 population). When it

comes to Public Assistance, the one-percentage-point increase in the unemployment rate resulted in about an additional 11.2 recipients and 10.5 recipient households per 100,000 population. Similar effect sizes for recipients and recipient households suggest that the majority of COVID-19-induced Public Assistance recipients may consist of single-person households.

The effect sizes for these safety net programs are far from negligible. In January 2000, just before the COVID-19 crisis, the number of Public Assistance recipient households excluding the households of the aged, the disabled, and the sick was about 255 per 100,000 population (National Survey on Public Assistance Recipients). On the other hand, the estimated increases per 100,000 population per one-percentage-point increase in the unemployment rate are around 80-90 applications for the temporary loan programs, about 28 applications for the Housing Security Benefit, and about 11 Public Assistant recipient households (per 100,000 population) in a month.

5 Further analyses

5.1 Robustness checks

As robustness checks, we present estimation results based on two model specifications (with or without individual linear trends $\phi_i t$ in equation (2)), two regression schemes (OLS or WLS), and two types of outcome variables (monthly or monthly year-on-year difference). The rationales for these robustness checks are (a) to examine whether estimation results change if we use a simpler model without individual linear trends, (b) to compare OLS and WLS estimates and discuss how they differ and why as Solon et al. [38] recommend, and (c) to control for prefecture-specific monthly fixed effects in addition to standard prefecture and monthly fixed effects.

Appendix C provides the estimation results of robustness checks for the suicide rates (Figure C.1), unemployment benefits (Figure C.2) and other safety net programs (Figure C.3) respectively. Overall, our primary findings for suicide and all the safety net programs seem plausible based on these different estimation settings. However, estimates for suicide are less robust and more imprecise when year-on-year differences are used as outcome variables. We also discuss these results in more detail in Appendix C.

5.2 An alternative treatment

In order to examine the characteristics of our main treatment variable based on the unemployment rate, we construct another employment-shock treatment variable based on a more limited employment indicator. That is, for the numerator of the regional unemployment rate X_{it} in the employment-shock equation (1), we use

the number of the unemployed people who are registered as full-time-job seekers at public employment security offices. Because it is expected that these registered full-time-job seekers are often the breadwinners of households and eligible for unemployment benefits, this alternative employment-shock variable may reflect a specific part of the entire employment shock in a prefecture.

In Appendix D, we present DID estimation results using this alternative treatment variable. Contrary to our main findings, estimates for suicide are not significantly different from zero (Figures D.2), but estimates for unemployment benefits are robustly positive and often significantly different from zero from July 2020 (Figure D.3). Estimates for the two temporary loan programs, the Housing Security Benefit, and Public Assistance are positive and in most cases significant in the COVID-19 period. (Figure D.4).

These results that are partly different from the baseline results may be explained by the fact that the alternative employment shocks reflect an unemployment increase in manufacturing industries whereas the baseline employment shocks are characterized as tertiary-industry shocks in metropolitan and service-sector regions. See further discussions in Appendix D.

6 Discussion and conclusion

Exploiting regional variations in the employment shocks caused by the COVID-19 crisis, this paper examines whether the COVID-19-induced employment shocks in the second quarter of 2020 have affected rates of suicide and safety net use in the second and third quarters of 2020.

Our estimation results suggest that the COVID-19-induced increase in unemployment has increased both the rate of suicide and the rate of safety net participation. Per 100,000 population and per month at peaks, the estimated effect sizes for a one-percentage-point increase in the unemployment rate are, approximately, an additional 0.393 suicides (or a 30.3 % increase in suicides), 89 and 82 recipients for the two temporary loan programs, 28 recipients for the Housing Security Benefit, and 11 recipients for Public Assistance.

All of these values are not socio-economically negligible. Let's consider a hypothetical region with a population of 10 million, which was roughly close to the populations of London (9.0 million), New York City (8.3 million), or Sweden (10.4 million) in 2020. Suppose that the COVID-19 crisis or a similar pandemic increases the unemployment rate of this region by one percentage point in a quarter in its early stage. In this region, this employment shock would then result in an additional 39 suicides, 8,900 and 9,200 recipients for the two temporary loan programs, 2,800 recipients of the Housing Security Benefits, and 1,100 recipients of Public Assistance in the last month or the next month of this quarter.

In particular, the estimated effect sizes for suicide rates in our analysis are much higher than the corresponding previous estimates. Although previous studies use different data (mostly cross-country or cross-region yearly panel data) and different research designs (including correlational studies without explicit empirical strategies), our baseline estimate of a 30.3% increase in the suicide rate caused by a one-percentage-point increase in the unemployment rate is much higher than has been observed in the past. For example, the baseline estimate in Ruhm [17] is a 1.3% increase in the suicide rate. A systematic review of Fransquilho et al. [28] examines and summarizes many related studies, some of which show that a one-percentage-point increase in the unemployment rate is associated with a 0.79-4.5% increase in the suicide rate, although this review does not systematically compare effect sizes in different studies. One reason behind our larger estimated effect size is that we use monthly panel data, adopt an event-study specification with time-varying estimates, and obtain the maximum monthly estimate in July 2020. Another possible reason is that the sharp employment shock under the COVID-19 crisis may have caused unusual short-term impact on suicide and suicidal ideation, likely in interaction with other factors.

Overall, although attitudes toward suicide and social safety net programs vary across countries and regions, our findings show the non-negligible magnitudes of mental and financial distress caused by the COVID-19-induced employment shocks. More precise interplay among unemployment, mental and financial distress, and safety net participation should be examined in future studies.

B   Variable definitions and Data sources

Table B.1: Variable definitions and data sources

Variable	Definition	Data source
Employment variable		
Employment rate (%)	Employed/Population aged 15+	Labour Force Survey
Labor force participation rate (%)	Labor force/Population aged 15+	Labour Force Survey
Unemployment rate (%)	Total unemployed population/Labor force	Labour Force Survey
Jobs-to-applicants ratio	Registered job offers/Registered unemployed	General Employment Placement Status
Registered-unemployed ratio (%)	Registered unemployed/Labor force	General Employment Placement Status
Outcome variable (per 100k)		
Total suicide rate	Total suicides/Population	Statistics of Suicide (MHLW)
Female suicide rate	Female suicides/Female population	Statistics of Suicide (MHLW)
Male suicide rate	Male suicides/Male population	Statistics of Suicide (MHLW)
Unemployment benefit recipients	Unemployment benefit recipients/Population	Monthly Report of Unemployment Insurance
Emergency Small Amount Funds	Accepted applications/Population	Provided by the central government
General Support Funds	Accepted applications/Population	Provided by the central government
Housing Security Benefit	Accepted applications/Population	Provided by the central government
Public Assistance recipients	Recipients/Population	National Survey on Public Assistance Recipients
Public Assistance recipient households	Recipient households/Population	National Survey on Public Assistance Recipients

Notes: For the employment rate, labor force participation rate, unemployment rate, and job-to-applicants ratio in Figure 1, seasonally adjusted data is used. For the monthly data of the unemployment rates that are used for the construction of the employment shocks based on equation (1), the data is not seasonally adjusted. For suicide rates and all the variables of safety net programs, nation-level data in Figure 1 and monthly-level data in Figure 2 and in Table 1 are based on raw data that are not seasonally adjusted. Prefecture-level aggregated suicide statistics based on residential addresses are also available, but we do not use these data due to the large number of missing values. In this paper we use the suicide statistics that were updated in December 2020. Some monthly total suicide numbers are updated in the original police statistics but not in the Statistics of Suicide by MHLW, but we use the latter data because it also provides gender-based suicide statistics. Note that estimation results for total suicide rates do not change much when we use the updated original police statistics.

C   Estimation results for robustness checks

As robustness checks, we present estimation results based on two model specifications (with or without individual linear trends $\phi_i t$ in eqaution (2)), two regression schemes (OLS or WLS), and two types of outcome variables (monthly or monthly year-on-year difference). Note that our baseline estimation is based on WLS estimation with individual linear trends using a monthly outcome variable.

The rationales for these robustness checks are as follows. First, while incorporating individual linear trends may be effective for controlling for observed and unobserved differential trends across prefectures, it is useful to examine whether estimation results change if we use a simpler model without individual linear trends. Second, as Solon et al.[38] argue, it is not clear a priori whether OLS or WLS regression is more suitable for estimating a population average effect, so we compare OLS and WLS estimates and discuss how they differ and why. Third, using a year-on-year outcome difference as an outcome variable is meant to control for prefecture-specific monthly fixed effects in addition to standard prefecture and monthly fixed effects in model (2).

Figures C.1, C.2 and C.3 provide additional estimation results using the two estimation methods (OLS or WLS), two model specifications (with or without prefecture linear trends), two outcome specifications (a monthly outcome or its year-on-year difference).

First, Figure C.1 shows the estimation results for the suicide rates. The left-hand graphs show estimates for monthly outcomes and the right-hand graphs present estimates for monthly year-on-year outcome differences. Results show that estimates are positive and often significantly different from zero for June and July 2020, but estimates with OLS regression or estimates for year-on-year outcomes tend to be smaller and sometimes statistically insignificant.

We interpret the smaller OLS estimates as reflecting heterogeneous employment-shock effects across prefectures: as Figure 2 indicates, prefectures with larger populations may be more clearly affected by the employment shocks and the WLS estimation put more weights on these prefectures. Smaller estimates for year-on-year outcomes suggest that COVID-19 employment shocks on suicide are not estimated robustly enough, but another interpretation is that controlling for prefecture-specific monthly fixed effects as well as prefecture and monthly fixed effects makes estimation more imprecise.

Second, Figure C.2 provides counterpart estimation results for unemployment benefits. It shows that the estimates for unemployment benefits are robustly not significantly different from zero in the COVID-19 period. However, gradually increasing OLS estimates in the COVID-19 period suggest the possibility that some positive impact of the employment shocks on unemployment benefits is not precisely captured by this data or this research design.

Third, Figure C.3 firstly shows that the baseline estimation results for the two temporary loan programs and Housing Security benefit are robust to different weighting schemes. Figure C.3 also indicates that the implications of the baseline results for Public Assistance recipients/recipient households do not change once individual linear trends are controlled for. However, pre-COVID-19 estimates for Public Assistance outcomes indicate the existence of differential trends if individual linear trends are not controlled for.

Figure C.1: DID estimates for suicides

Notes: Each plot indicates a point estimate and a vertical line indicates a 90% confidence interval. The treatment variable is the COVID-19-induced employment shock, which is calculated as equation (1). A year-on-year outcome variable (right graphs) is calculated as the difference between an outcome value at month t and an outcome value at month $t-12$. WLS estimation is weighted by prefecture population size. Estimation "with trends" incorporates individual (i.e. prefecture) linear trends and time-varying estimates can be obtained from February 2019 with this model specification.

Figure C.2: DID estimates for unemployment benefits

Notes: Each plot indicates a point estimate and a vertical line indicates a 90% confidence interval. The treatment variable is the COVID-19-induced employment shock, which is calculated as equation (1). A year-on-year outcome variable (right graphs) is calculated as the difference between an outcome value at month t and an outcome value at month $t-12$. WLS estimation is weighted by prefecture population size. Estimation "with trends" incorporates individual (i.e. prefecture) linear trends and time-varying estimates can be obtained from February 2019 with this model specification.

Figure C.3: DID estimates for safety net programs

Notes: Each plot indicates a point estimate and a vertical line indicates a 90% confidence interval. The treatment variable is the COVID-19-induced employment shock, which is calculated as an increase in the prefecture-level unemployment rate from the second quarter of 2019 to the second quarter of 2020. A year-on-year outcome variable is calculated as the difference between an outcome value at month t and an outcome value at month $t-12$. WLS estimation is weighted by prefecture population size. Estimation "with trends" for the outcome of Public Assistance incorporates individual (i.e. prefecture) linear trends and time-varying estimates can be obtained from February 2019 with this model specification. For the outcomes of accepted applications for the temporary loan programs and the Housing Security Benefit (panels (a)-(c)), individual linear trends are not introduced due to discontinuously smaller outcome values in the pre-COVID-19 period. For the outcome of the accepted applications for the Housing Security Benefit, the reference month is March 2019 instead of January 2020 due to the lack of data.

D An alternative treatment variable

In this appendix, we provide estimation results using an alternative employment-shock variable. More specifically, for the numerator of X_{it} in the employment-shock equation (1), we use the number of unemployed people who are registered as full-time-job seekers at public employment security offices called *Hello Work*, instead of the total number of the unemployed.

There are also some advantages of using this alternative employment-shock variable. First, registered unemployed people include all the unemployed who receive or will receive unemployment benefits, implying that this alternative employment-shock variable strongly reflects the COVID-19 shocks for those who are entitled to receive unemployment benefits.[1] Second, it is expected that the registered unemployed who seek full-time jobs are often the breadwinners of households, not part-time or contingent workers. We thus may be able to capture the COVID-19 shocks for these core workers by using this alternative treatment variable.

Note that although X_{it} is quarterly in the baseline definition (1), we use the number of the registered full-time-job seekers in June for the second quarter and December for the fourth quarter. This is because the year-on-year total numbers of registered job seekers sharply dropped in April and May 2020 and increased in June 2020, probably due to the declaration of the State of Emergency in April and May 2020.[2]

As Figure D.1 shows, there is no clear correlation between the regional variations in the baseline employment shock and the alternative employment shock (R squared is 0.04 and the estimated slope is not significantly different from zero at the 10 % significance level). This is counter-intuitive given that registered unemployed people at *Hello Work* should be, at least conceptually, counted as unemployed people in the unemployment rate.

A plausible explanation of this unclear correlation is that a group of prefectures that have large manufacturing areas experienced the largest alternative employment shocks but relatively small baseline employment shocks, making the correlation obscure. In fact, in Figure D.1, the alternative employment shocks (Y axis) for some prefectures with major manufacturing regions are among the largest (e.g. Gifu, Aichi, Shizuoka, Shiga, Hiroshima, Toyama,and Mie). But the baseline employment shocks (X axis) for them are much smaller than the corresponding shocks for prefectures in metropolitan areas or with popular sightseeing spots that have

---

[1]To receive unemployment benefits, an unemployed person needs to be registered at *Hello Work*.

[2]We also note that this alternative "unemployment rate" with the registered unemployed is not commonly used because the numerator (the number of registered unemployed job seekers) and the denominator (total labor force) are based on different surveys. We nonetheless argue that it is useful to use this alternative variable for the further examination of the COVID-19 shocks.

high tertiary (or service-sector) industry ratios (Okinawa, Kanagawa, Osaka, Nara, Hokkaido, Hyogo, Tokyo, Saitama, Chiba, and Kyoto).

In other words, the baseline employment shocks are strongly related to the service-sector industry whereas the alternative employment shocks are associated with the manufacturing industry. In fact, simple regression analyses show that there is significant positive correlation between the service-sector employment rate and the baseline employment shocks and significant positive correlation between the manufacturing employment rate and the alternative employment shocks.

Figure D.1: Correlation between employment-shock variables

The sizes of each circle and prefecture name are based on the population size of each prefecture. The dashed line is the fitted linear regression line based on the ordinary least square (OLS) method.

We provide estimation results using the alternative treatment variable in the same manner as Appendix C. First, Figure D.2 shows the estimation results for the suicide rates. Although some estimates in the COVID-19 period are significantly different from zero, estimates tend to fluctuate both before and during the COVID-19 crisis and we do not observe robust estimation results. This means that a prefecture having a higher alternative employment shock does not result in a higher suicide rate.

Second, Figure D.3 shows that estimates for total, female, and male unemployment benefits are robustly significantly different from zero in the third quarter

(July-September) of 2020. These results are in contrast with those of robustness checks with the baseline treatment variable (Figure C.2), but this is understandable given the fact that the alternative employment shock is more directly related to the COVID-19 shocks on unemployed people who are eligible for the unemployment benefit than the baseline unemployment rate as mentioned above.

Third, Figure D.4 shows that estimates for the two temporary loan programs, the Housing Security Benefit and Public Assistance outcomes are positive and mostly significantly different from zero in the COVID-19 period. Although some non-zero estimates for Public Assistance outcomes in the pre-COVID-19 period suggest that some confounding differential trends may not be properly controlled for, the overall trends of the estimates imply that the alternative employment shock should have some positive impact on the numbers of Public Assistance recipients and recipient households.

Overall, we observe that the alternative COVID-19 employment shock measured by full-time-job seekers clearly affects safety net participation, but not suicide. Note that these results do not change when we further control for the baseline treatment variable. We speculate that this absence of an effect on suicide is related to the socio-economic status of full-time-job seekers, including their eligibility for unemployment benefits, but further investigation is required.

Figure D.2: DID estimates for suicides (alternative employment shock)

Notes: Each plot indicates a point estimate and a vertical line indicates a 90% confidence interval. The treatment variable is the COVID-19-induced employment shock, which is calculated as equation (1) but the numerator of X_{it} is the number of registered full-time-job seekers. A year-on-year outcome variable (right graphs) is calculated as the difference between an outcome value at month t and an outcome value at month $t-12$. WLS estimation is weighted by prefecture population size. Estimation "with trends" incorporates individual (i.e. prefecture) linear trends and time-varying estimates can be obtained from February 2019 with this model specification.

Figure D.3: DID estimates for unemployment benefits (alternative employment shock)

Notes: Each plot indicates a point estimate and a vertical line indicates a 90% confidence interval. The treatment variable is the COVID-19-induced employment shock, which is calculated as equation (1) but the numerator of X_{it} is the number of registered full-time-job seekers. A year-on-year outcome variable (right graphs) is calculated as the difference between an outcome value at month t and an outcome value at month $t-12$. WLS estimation is weighted by prefecture population size. Estimation "with trends" incorporates individual (i.e. prefecture) linear trends and time-varying estimates can be obtained from February 2019 with this model specification.

Figure D.4: DID estimates for safety net programs (alternative employment shock)

Notes: Each plot indicates a point estimate and a vertical line indicates a 90% confidence interval. The treatment variable is the COVID-19-induced employment shock, which is calculated as equation (1) but the numerator of X_{it} is the number of registered full-time-job seekers. A year-on-year outcome variable is calculated as the difference between an outcome value at month t and an outcome value at month $t-12$. WLS estimation is weighted by prefecture population size. Estimation "with trends" for the outcome of Public Assistance incorporates individual (i.e. prefecture) linear trends and time-varying estimates can be obtained from February 2019 with this model specification. For the outcomes of accepted applications for the temporary loans and the Housing Security Benefit (panels (a)-(c)), individual linear trends are not introduced due to discontinuously smaller outcome values in the pre-COVID-19 period. For the outcome of the accepted applications for the Housing Security Benefit, the reference month is March 2019 instead of January 2020 due to the lack of data.
