26 **Abstract**

27 Curtailing the Spring 2020 COVID-19 surge required sweeping and stringent interventions by
28 governments across the world. Wastewater-based COVID-19 epidemiology programs have been initiated
29 in many countries to provide public health agencies with a complementary disease tracking metric and
30 facile surveillance tool. However, their efficacy in prospectively capturing resurgence following a period of
31 low prevalence is unclear. In this study, the SARS-CoV-2 viral signal was measured in primary clarified
32 sludge harvested every two days at the City of Ottawa's water resource recovery facility during the
33 summer of 2020, when clinical testing recorded daily percent positivity below 1%. In late July, increases
34 of >400% in normalized SARS-CoV-2 RNA signal in wastewater were identified 48 hours prior to reported
35 >300% increases in positive cases that were retrospectively attributed to community-acquired infections.
36 During this resurgence period, SARS-CoV-2 RNA signal in wastewater preceded the reported >160%
37 increase in community hospitalizations by approximately 96 hours. This study supports wastewater-based
38 COVID-19 surveillance of populations in augmenting the efficacy of diagnostic testing, which can suffer
39 from sampling biases or timely reporting as in the case of hospitalization census.

40 **Keywords:** COVID-19; wastewater-based epidemiology; SARS-CoV-2, virus, resurgence, wave

41 **1. Introduction**

42 The COVID-19 global pandemic has profound impacts on day-to-day life through sickness, death
43 and also the economic and social effects of lockdowns, closures and curfews put in place by local
44 governments to control and limit the community spread of the disease. COVID-19 surveillance
45 approaches invoked by nations around the world include case ascertainment of individual patients and
46 include nucleic acid-based tests, serological tests and contact tracing. The objective of this study is to
47 investigate early identification of COVID-19 infection resurgence in Ottawa (Ontario, Canada), using
48 SARS-CoV-2 viral RNA signal in primary sludge wastewater.

49 Wastewater-based epidemiology (WBE) is a potential surveillance tool to obtain a rapid measure
50 of COVID-19 infection in the population at large. Fecal shedding of SARS-CoV-2 viral particles has been
51 shown to occur before, during and after active COVID-19 infection, for periods ranging from a few days to
52 several weeks (Chen et al., 2020; Cheung et al., 2020; Xing et al., 2020; Xu et al., 2020), with current
53 literature suggesting that children may shed viral particles longer than adults (Li et al., 2020; Ma et al.,
54 2020). Fecal shedding of SARS-CoV-2 viral particles in stool occurs in patients infected with COVID-19
55 and appears to be independent of the presence of SARS-CoV-2 viral particles in the upper respiratory
56 tract. As WBE initiatives rely on the fecally shed viral particles (Collivignarelli et al., 2020; Lodder and de
57 Roda Husman, 2020), an understanding of the predictive ability of this epidemiological metric is
58 necessary for public health units to appropriately action this tool (Hart and Halden, 2020; Hill et al., 2020;
59 Thompson et al., 2020). In particular, studies to date that demonstrate the potential for WBE to identify
60 the onset of community infection prior to clinical testing have largely been applied to identifying first wave
61 of the disease in community (Kaplan et al., 2020; La Rosa et al., 2020; Medema et al., 2020; Nemudryi et
62 al., 2020; Peccia et al., 2020; Sherchan et al., 2020; Vallejo et al., 2020; Wu et al., 2020). Due to limited
63 clinical testing in many countries during the onset of COVID-19 and limited use of wastewater-based
64 SARS-CoV-2 surveillance, it remains unclear whether WBE can have a role in identifying COVID-19
65 resurgences. The objectives of this study are to establish a relationship between: i) increases in SARS-
66 CoV-2 RNA signal in wastewater, ii) increases in the number of new COVID-19 positive patient cases in

67 the community, and iii) increases in the number of new hospitalizations of COVID-19 positive patients in
68 the community.

69 **2. Materials and methods**

70 **2.1. Characteristics of the City of Ottawa's water resource recovery facility**

71 Primary clarified sludge samples were harvested from the City of Ottawa's Robert O. Pickard
72 Environmental Centre, in Ottawa, ON, which services approximately 1.0M residents of the national capital
73 region. The hydraulic residence time of the Ottawa sewershed ranges from 2 hours to 35 hours, with an
74 average residence time of approximately 12 hours. The Ottawa water resource recovery facility (WRRF)
75 has an average daily flow of 435,000 m³ per day. The facility is comprised of preliminary treatment
76 consisting of coarse and fine screening and grit chambers for the removal of larger particles. The primary
77 treatment units consist of rectangular primary clarifiers and the secondary treatment is a conventional
78 activated sludge system operating without nitrification. Finally, chlorination is used as a disinfection
79 method followed by dechlorination prior to discharge to receiving waters.

80 **2.2. Sample collection, concentration, extraction and quantification**

81 24-hour composite samples of primary clarified sludge (PCS) were collected from the Ottawa
82 WRRF at a frequency of every 2 days for a six-week period, from June 20th, 2020 until August 4th, 2020.
83 Concentration of samples, extraction of nucleic acids and quantification of SARS-CoV-2 N1 and N2 gene
84 regions were performed according to D'Aoust et al. (2020). It has been previously observed that
85 normalization of SARS-CoV-2 viral copies with pepper mild mottle virus (copies SARS-CoV-2/copies
86 PMMoV) was used to normalize viral SARS-CoV-2 signal for variations in wastewater chemico-physical
87 characteristics, plant flows, wastewater solids organic/inorganic ratio and PCR amplification (D'Aoust et
88 al., 2020). Evaluation of viral recovery efficiency was also performed as per D'Aoust et al. (2020); with the
89 data in this study not being corrected for recovery efficiency. Dilution tests were periodically performed to
90 determine if inhibition was present in the samples. The method's limit of detection for the N1 and N2 gene
91 regions was determined by determining the concentration at which a detection rate of $\geq 95\%$ (<5% false
92 negatives) was obtained, as per the MIQE recommendations (Bustin et al., 2009). Additionally, samples
93 were discarded if they did not meet the following requirements: 1) standard curves are linear ($R^2 \geq 0.95$),
94 2) the copies/well are found in the linear range of the standard curve, and 3) the primer efficiency was

95 between 90%-130%. Additionally, all samples were analyzed in triplicate and samples with values greater
96 than 2 standard deviations away from the mean were discarded.

97 **2.3. COVID-19 epidemiological data**

98 **Clinical epidemiological data**

99 During the study period, there were two main methods of COVID-19 surveillance. The first
100 method was to observe the daily number of new confirmed COVID-19 infections, determined via
101 laboratory-confirmed SARS-CoV-2 tests using reverse transcriptase-quantitative polymerase chain
102 reaction (RT-qPCR) that targeted the RNA-Dependent RNA polymerase for multiple genes. Tests were
103 classified as positive for SARS-CoV-2 infection if at least one of any of the two gene “targets” were
104 detected (Government of Ontario, 2020). There was a notable increase in COVID-19 testing in Ottawa
105 during early June with an average daily testing increase from approximately 270 tests per day to
106 approximately 800 tests per day. As a result of increased testing resources, testing was predominantly
107 performed at dedicated community clinics, physician offices and in hospitals, retirement homes and long-
108 term care facilities.

109 The second method used for COVID-19 surveillance was the daily hospital census counts,
110 defined as the number of patients residing in Ottawa with confirmed COVID-19 infections at midnight to
111 any of Ottawa five acute care hospitals that accepted COVID-19 patients. The average length of stay
112 during the study period was 19.5 days, interquartile range 22 days.

113 Additional methods used for surveillance of COVID-19 infection is are the number of daily cases
114 and test positivity. These metrics are commonly communicated to the public. COVID-19 test positivity is
115 the proportion of positive COVID-19 cases as a percent of all individuals tested for COVID-19 on a
116 specific date. Confirmed COVID-19 cases and positivity were examined using daily counts based on the
117 date of the test reported for Ottawa residents and seven-day mid-point average.

118 **2.4. Statistical analysis**

119 In order to test for significance and for strength of correlation between SARS-CoV-2 RNA signal
120 and epidemiological metrics, a student's t-test and Pearson's correlation analyses were performed, with a
121 p -value of 0.05 or lower signifying significance.

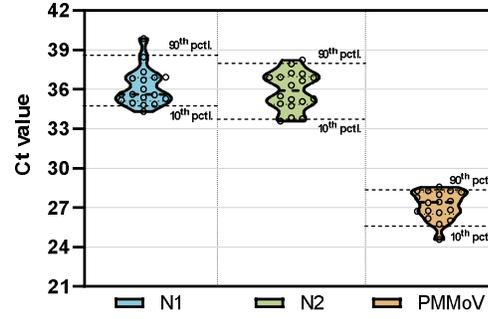

122 To evaluate if a lag existed between the appearance of increased SARS-CoV-2 RNA signal in
123 wastewater and epidemiological metrics, time-step analyses were also performed where the correlations
124 between viral RNA signal and epidemiological metrics were offset by a period of 1 to 7 days. The time-
125 step analysis was performed across three discreet time-periods: i) pre-resurgence and resurgence,
126 ending after the resurgence (June 21st to July 21st), ii) pre-resurgence and post-resurgence, extending to
127 the end of the data set (June 21st to July 25th) and iii) full data period (June 21st to August 4th).

128 **3. Results, discussion and implications**

129 **3.1. Trend and peak of wastewater SARS-CoV-2 RNA viral level and other** 130 **COVID-19 surveillance metrics**

131 All conventional COVID-19 surveillance measures increased during the study period from a low
132 level at the beginning of the study. The number of daily cases and percent positive cases was highest on
133 July 19, with a 326% relative increase from the preceding 7-day period. Meanwhile, current hospitalized
134 patient cases were at their highest on July 31-Aug 2 with a 168% increase compared to the week of July
135 13 (Figure 2 a-d).

136 PMMoV normalized SARS-CoV-2 viral copies, a metric outlined in an earlier publication (D'Aoust
137 et al., 2020), normalizes SARS-CoV-2 viral copies by the number of copies of PMMoV in wastewater, and
138 is effective due to the great temporal stability of PMMoV, as demonstrated in Figure 1, below.
139 Additionally, dilution tests demonstrated that the sample PCR was not inhibited.

140

141 Figure 1: Ct values of the SARS-CoV-2 N1 and N2 gene regions, and the PMMoV normalization gene (1:10 dilution
142 shown), outlining the greater stability of PMMoV, justifying its use as a normalization gene. The 10th and 90th
143 percentile are displayed, along with the median (dotted line inside shapes).

144

145 Similarly to other epidemiological metrics, the PMMoV normalized viral signal in Ottawa's
146 wastewater was also shown to be low at the beginning of the study period through to the week of July 13
147 with both N1 and N2 regions below 1.00×10^{-4} copies/copies PMMoV. There was a 450% relative increase
148 ($p < 0.05$) in N1 and 440% increase ($p < 0.05$) in N2 viral regions on July 17 to 19 compared to July 13 to
149 15. The absolute increase of 2.03×10^{-4} and 3.01×10^{-4} copies/copies PMMoV was reported during this
150 period of increase for N1 and N2 gene regions, respectively (Figure 2e). The wastewater-based
151 epidemiological metric in this study was not corrected for recovery percentages.

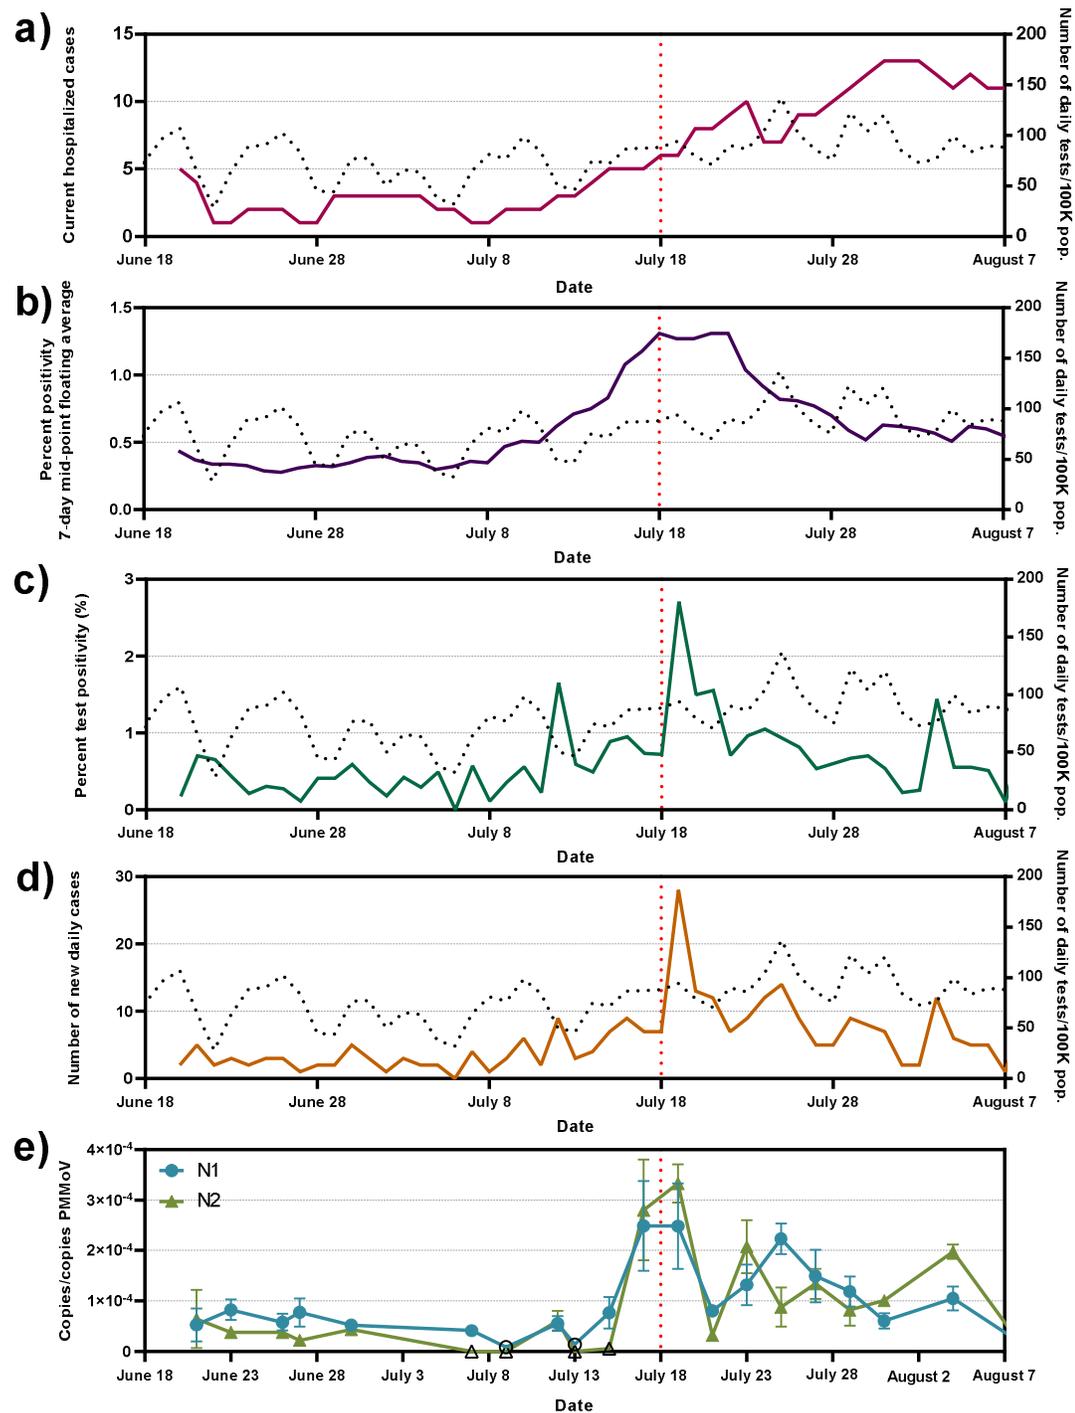

Figure 2: Epidemiological metrics and SARS-CoV-2 viral concentrations over the study period; a) COVID-19-caused hospitalizations, b) percent test positivity (7-day mid-point floating average), c) percent test positivity and d) number of new daily cases, along with e) wastewater SARS-CoV-2 N1 and N2 gene copies/PMMoV gene copies. Open data points signify points which were below the limit of quantification.

154 **3.2. Correlation between surveillance metrics**

155 Positive correlations were observed (Figure 2 c, d and e) between the normalized viral RNA
156 signal and both the number of new daily positive COVID-19 cases (N1: $R = 0.673$, $p < 0.001$; N2: $R =$
157 0.648 , $p < 0.001$) and clinical testing percent positivity (N1: $R = 0.468$, $p < 0.001$; N2: $R = 0.404$, $p < 0.001$).
158 These findings are in agreement with reported observations from previous studies (D'Aoust et al., 2020;
159 Nemudryi et al., 2020; Peccia et al., 2020). This study, as opposed to an earlier study in the same region
160 (D'Aoust et al., 2020), demonstrates that strong correlations do in fact exist between viral RNA signal and
161 the epidemiological metric of clinical daily new COVID-19 cases, as supported by several other studies
162 (Hart and Halden, 2020; Michael-Kordatou et al., 2020; Trottier et al., 2020; Wu et al., 2020). The
163 moderate correlations between viral RNA signal and clinical daily new COVID-19 cases in previous work
164 was largely attributed to inadequate resources to achieve a developed clinical testing framework early in
165 the pandemic (lower daily # of tests). In this study, a strong testing regiment was deployed in Ottawa and
166 hence produced a more reliable daily new COVID-19 cases metric across this study period. A moderately
167 weak positive correlation exists between N1 and N2 SARS-CoV-2 PMMoV-normalized RNA signal and
168 COVID-19-caused hospitalizations ($R = 0.347$, $p < 0.001$ and $R = 0.464$, $p < 0.001$ for N1 and N2,
169 respectively; Figure 2 a and e).

170 **3.3. Temporal association between surveillance metrics**

171 A visual comparison of clinical testing percent positivity and the number of new daily positive
172 COVID-19 cases compared to the PMMoV-normalized RNA signal shows that the viral RNA signal
173 predates both the clinical testing percent positivity and new daily positive COVID-19 cases
174 epidemiological data. A times-step correlation shows the strongest correlation for a two-day step between
175 SARS-CoV-2 viral RNA signal and both the number of new daily positive COVID-19 cases and the clinical
176 testing percent positivity (N1: $R = 0.703$, $p < 0.001$; N2: $R = 0.721$, $p < 0.001$ N1: $R = 0.703$, $p < 0.001$; N2: R
177 $= 0.714$, $p < 0.001$) (Table 1). The strong correlation for hospitalized cases is observed after a time-step of
178 four days (N1: $R = 0.741$, $p < 0.001$; N2: $R = 0.767$, $p < 0.001$). The precedence of viral RNA signal vs.
179 other epidemiological metrics has been reported recently by other earlier studies (Chavarria-Miró et al.,
180 2020; Kumar et al., 2020; Peccia et al., 2020).

It is made available under a [CC-BY-NC-ND 4.0 International license](https://creativecommons.org/licenses/by-nc-nd/4.0/) .

181 Table 1: Time-step analyses of correlations (Pearson's R) between normalized SARS-CoV-2 viral RNA signal
 182 (copies/copies PMMoV) and 7-day rolling average percent positivity, test percent positivity and daily new cases
 183 epidemiological metrics.

184

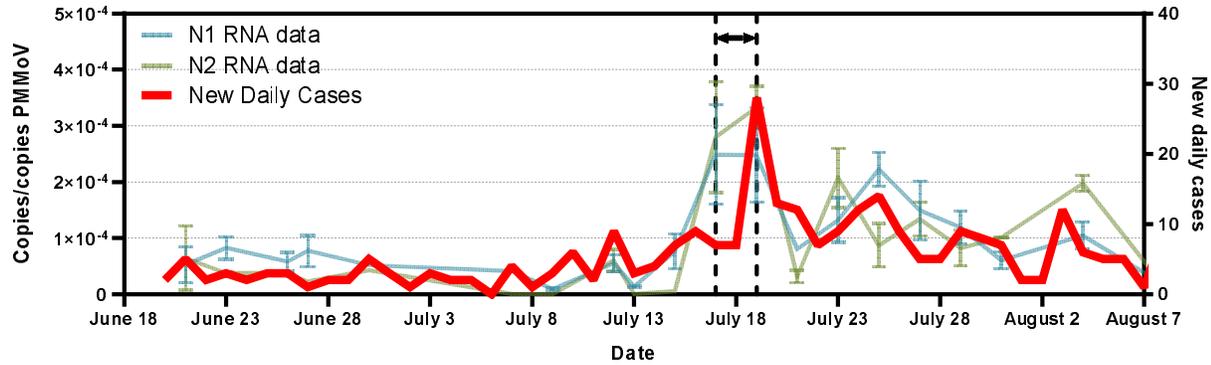

Figure 3: Figure of the new daily cases epidemiological metric (in red) with SARS-CoV-2 viral RNA signal in Ottawa's primary clarified sludge samples, with the precedence of SARS-COV-2 viral signal in wastewater clearly outlined.

185 This observation is supported by, and confirms earlier studies (Chavarria-Miró et al., 2020; Kumar
186 et al., 2020; Peccia et al., 2020). Recent studies proposed that viral SARS-CoV-2 RNA data may in fact
187 precede hospital admissions by 1 to 4 days in primary sludge (Figure 3) (Peccia et al., 2020), and 6-14
188 days in raw wastewater (Kumar et al., 2020). This could signify that hospitalizations may begin peaking
189 four days after an increased viral RNA signal, with the caveat that hospitalizations rates may be
190 significantly higher when viral RNA signal is the result from shedding of an at-risk population group
191 (young infants, elderly, immunocompromised, etc.). In addition, the RNA signal post-resurgence indicates
192 that the resurgence events in viral RNA signal serves to weaken the correlation of subsequent peaks with
193 clinical testing metrics. It is hypothesized that early and later infections and overlapping shedding events
194 of duration and intensity convolute peaks within a period of time following the initial new peaks/surges in
195 COVID-19 infections. Nonetheless, the RNA epidemiological metric of copies/copies PMMoV may
196 become extremely valuable to public health units in their preparation for the next COVID-19 wave.

197 **4. Conclusions**

198 This study demonstrates that due to the general stability of SARS-CoV-2 RNA measurements in
199 PCS, this fraction of wastewater can reliably be utilized to predict rapid increases or resurgences in
200 COVID-19 cases in the community at large (Alpaslan-Kocamemi et al., 2020; D'Aoust et al., 2020; Peccia
201 et al., 2020), and the results strongly suggests that PCS can be utilized as part of sentinel-type
202 wastewater based epidemiology endeavors at WRRFs.

203 Advantages of this approach include: i) the analyses in water resource recovery facilities are
204 high-enrollment surveys, which capture a majority of the urban population, regardless of individual's
205 reluctance to get tested clinically; ii) tests are anonymous and do not pose ethical challenges as opposed
206 to mass clinical testing or targeted sewershed monitoring efforts; iii) data can be used as a confirmation to
207 clinical tests, increases the effectiveness of local public health units and data remains independent of
208 official testing strategies or media sentiment, and iv) provides an exit strategy/path forward for public
209 health units as something to eventually transition to once immunization is available, to cut down on
210 clinical testing costs, while maintaining broad surveillance capabilities. However, limitations to this WBE
211 approach includes the following: i) data obtained only gives high-altitude view of the situation in the
212 community, and it is currently not possible to correlate this data to an actual number of cases in the
213 community; ii) testing protocols must be optimized and retain sensitivity at very-low levels of disease
214 incidence to remain relevant; iii) widespread adoption of WBE requires scale-up of public health units'
215 current capabilities and/or partnership with private laboratories or research institutions, and iv) increases
216 in resolution (more localized, upstream of water resource recovery facilities, for example) of tests in
217 watersheds may lead to ethical questions for public health unit if it wishes to act upon the data, due to the
218 potential risk for identifying or singling out small subgroups of a population. It is noted however that these
219 issues are not dissimilar to other ethical issues currently existing with other COVID-19 public health
220 endeavors, such as COVID-19 potential exposure notification smartphone applications.

333 6. Supplemental Material

334 Supplementary Table 1: List of PCR primer and probe sets utilized in this study.

Primer/probe & supplier	Sequence	Reference
<i>2019-nCoV_N1 forward primer (IDT)</i>	GAC CCC AAA ATC AGC GAA AT	(CDC, 2020)
<i>2019-nCoV_N1 reverse primer (IDT)</i>	TCT GGT TAC TGC CAG TTG AAT CTG	(CDC, 2020)
<i>2019-nCoV_N1 probe (IDT)</i>	6-FAM-ACC CCG CAT/ZEN/ TAC GTT TGG TGG ACC-IOWA BLACK FQ	(CDC, 2020)
<i>2019-nCoV_N2 forward primer (IDT)</i>	TTA CAA ACA TTG GCC GCA AA	(CDC, 2020)
<i>2019-nCoV_N2 reverse primer (IDT)</i>	GCG CGA CAT TCC GAA GAA	(CDC, 2020)
<i>2019-nCoV_N2 probe (IDT)</i>	6-FAM-ACA ATT TGC/ZEN/CCC CAG CGC TTC AG-IOWA BLACK FQ	(CDC, 2020)
<i>PMMoV forward primer (ABI)</i>	GAG TGG TTT GAC CTT AAC GTT GA	(Lee et al., 2018)
<i>PMMoV reverse primer (ABI)</i>	TTG TCG GTT GCA ATG CAA GT	(Lee et al., 2018)
<i>PMMoV probe (ABI)</i>	6-FAM-CCT ACC GAA GCA AAT G-MGB	(Lee et al., 2018)
