18

19

20 **Abstract**

21 **Objectives**

22 This systematic review and meta-analysis synthesized the evidence on the impact of
23 demographics and comorbidities with clinical outcomes of COVID-19, including severe
24 illness, admission to the intensive care unit (ICU), and death.

25 **Methods**

26 The PRISMA guidelines were followed to conduct and report this meta-analysis. The
27 protocol is registered in PROSPERO International prospective register of systematic
28 reviews (ID=CRD42020184440). Two authors independently searched literature from
29 PubMed, Embase, Cochrane library and CINHALL on May 6, 2020; removed duplicates;
30 screened titles, abstracts and full text using criteria; and extracted data from eligible articles.
31 A random-effects model was used to estimate the summary odds ratio (OR). Variations
32 among studies were examined using Cochrane Q and I^2 .

33 **Results**

34 Out of 4,275 articles obtained from the databases and screened, 71 studies that involved
35 216,843 patients were abstracted and then, where appropriate, analyzed by meta-analysis.
36 The COVID-19 related outcomes reported were death in 26 studies, severe illness in 41
37 studies, and admission to ICU in 11 studies. Death was significantly correlated with
38 hypertension (OR 2.60, 95% CI 1.95–3.25, $I^2 = 52.6%$, $n = 13$ studies), cardiovascular disease
39 (5.16, 4.10–6.22, 0.0%, 6), diabetes (2.11, 1.35–2.87, 67.4%, 12), chronic respiratory disease
40 (2.83, 2.14–3.51, 0.0%, 9), cerebrovascular diseases (5.14, 1.08–9.19, 0.0%, 2), male sex

41 (1.34, 1.18 – 1.50, 38.7%, 16), age older than 60 (6.09, 3.53 – 8.66, 95.5%, 6) or 65 years
42 (3.56, 1.21 – 5.90, 18.2%, 6). Severe illness was also significantly associated with
43 hypertension (1.70, 1.30 – 2.10, 47.8%, 21), cardiovascular diseases (2.04, 1.01–3.08, 30.6%,
44 10), diabetes (1.65, 1.23–2.08, 24.9%, 18), male sex (1.35, 1.23 – 1.47, 0.0%, 32) and age at
45 least 60 (4.91, 1.35 – 8.47, 0.0%, 4) or 65 (2.55, 1.94 – 3.17, 24.5%, 9) years. Among
46 hospitalized patients, the odds of admission to ICU was greater in individuals who had
47 cardiovascular diseases (1.36, 1.04–1.69, 0.0%, 4), diabetes (1.55, 1.20–1.90, 0.0%, 5) and
48 chronic respiratory disease (1.52, 1.09–1.94, 0.0%, 5) than those who were not having these
49 comorbidities.

50 **Conclusions**

51 Older age and chronic diseases increase the risk of developing severe illness, admission to ICU
52 and death among COVID-19 patients. Special strategies are warranted to prevent SARS-CoV-2
53 infection and manage COVID-19 cases in those with vulnerabilities.

62

63 **Introduction**

64 While the numbers of COVID-19 pandemic are a moving target, over 27 million have been
65 infected worldwide, with more than 881 thousand deaths as of September 7, 2020 [1]. Due
66 to potential differences in immunity and genetics, the clinical course of SARS-CoV-2
67 infection and related death is expected to vary with human health and demography status [2-
68 4]. However, precise factors of importance and their relative roles are not well defined.
69 Study findings on population groups that are more susceptible to severe illness and risk
70 factors for the clinical outcomes in COVID-19 patients remain contradictory [5-9]. While
71 some studies reported an increased risk of developing severe illness and death in COVID-19
72 patients with hypertension [5-7], cardiovascular diseases [5,7], diabetes [5,6], chronic
73 respiratory diseases [5,6], cancer [6], chronic kidney diseases [6], cerebrovascular disease
74 [6], smoking history [8], ages older than 60 years [7], and male gender [7], a limited
75 number of studies reported lack of correlation between these comorbidities and disease
76 progression or clinical outcomes in COVID-19 patients [9, 10].

77 Meta-analyses that examined predictors of severe illness and death in COVID-19 patients
78 involved data generated mainly from China and were based on a small number of studies (<15)
79 [11-13]. Although two meta-analyses summarized data based on China, Europe and the USA
80 [14,15], one of these did not examine the effect of some important comorbidities such as cancer,
81 chronic liver disease, and cerebrovascular disease on the risk of admission in ICU or other
82 clinical outcomes [14], the other one searched articles available only in PubMed [15], and both at
83 the time of this submission were not peer-reviewed and are preliminary in nature [14,15]. The

84 relevant literature important to incorporate in systematic review continues to grow, as our
85 collective experience with COVID-19 grows. A better understanding of both striking and
86 subtle variations in patients and their circumstances and their experience with SARS-CoV-2
87 infection would inform the continued development of improved interventions to reduce
88 morbidity and mortality from COVID-19. Therefore, following PRISMA guidelines, we
89 systematically summarized and assessed literature published before May 6, 2020, and where
90 appropriate to the data, conducted a meta-analysis of risk factors of severe illness,
91 admission to ICU, and death among COVID-19 patients.

92 **Methods**

93 **Protocol and registration**

94 A protocol developed following the Preferred Reporting Items for Systematic Reviews and
95 Meta-analyses (PRISMA) checklist guided the execution and reporting of this meta-analysis (S1
96 Table) [16]. The protocol is registered in PROSPERO International prospective register of
97 systematic reviews (ID=CRD42020184440) [17].

98 **Inclusion and Exclusion criteria**

99 All retrospective, cross-sectional, and prospective clinical and epidemiological studies except
100 individual case studies (comprehensive inclusion case series allowed), which reported the
101 prevalence or odds of death, severe illness, or admission to ICU and stratified by comorbidities
102 or demographic status among COVID-19 patients were included in the meta-analysis.
103 Unpublished studies and non-peer-reviewed preprints in repositories, case studies with fewer
104 than 10 samples or reports, letters, conference abstracts, protocol, gray literature, review

105 protocols and articles, irrelevant studies (on different topics), and animal or *in vitro* studies were
106 excluded. However, these sources were used to find additional eligible studies.

107 **Outcome and exposure measures**

108 The primary outcome was death. Secondary outcomes were severe illness and admission to ICU.
109 Severe illness was defined as having one of the following: SpO₂ <94%; respiratory rate >30
110 breaths per minute; lung infiltrates in >50% of lung fields by either plain or computed
111 tomography radiography; arterial partial pressure of oxygen to fraction of inspired oxygen
112 (PaO₂/FiO₂) <300 mmHg; or, organ dysfunction. Organ dysfunction include respiratory failure
113 as evidenced by mechanical ventilation, myocardial injury as evidenced by the need for
114 catheterization or troponin elevation, renal injury as evidenced by the need for dialysis or a 50%
115 decrease in renal function as assessed by either creatinine rise or decline in glomerular filtration
116 rate, hepatic failure, pulmonary embolus, or stroke/ cerebrovascular accident [18].

117 The exposure variables were demographic (age, gender, tobacco use) and comorbidities,
118 including hypertension, diabetes, cardiovascular disease, chronic respiratory disease, chronic
119 kidney disease, chronic liver disease, cerebrovascular disease, and cancer.

120 **Search methods for identification of studies**

121
122 An article search was conducted in parallel in PubMed, Embase, Cochrane Library, and
123 CINAHL. The search terms were (obesity OR hypertension OR Asthma or nutrition OR age OR
124 gender OR ethnicity OR race OR income OR poverty OR pregnancy OR “Breastfeeding” OR
125 “medical conditions” OR medications OR "chronic diseases" OR influenza or stroke OR HIV
126 OR cancer OR diabetes OR “cardiovascular disease” OR “coronary heart disease” OR “chronic

127 respiratory disease” OR “Sequential Organ Failure Assessment” OR smoking OR “co infection”
128 OR comorbidity OR comorbidities or risk) AND (clinical OR severe OR complications OR
129 mortality OR DEATH) AND (“coronavirus disease 2019” OR “COVID-19” OR “Severe acute
130 respiratory syndrome coronavirus 2” OR SARS-CoV-2 OR “Coronavirus 2” OR “2019 novel
131 coronavirus”). Additional details of the search are available in the supplementary files (S2
132 Table). After transferring articles searched from the four databases to RefWorks and removing
133 duplicates, the titles and abstracts were screened based on the inclusion and exclusion criteria.
134 Articles approved for full-text review were further screened based on eligibility criteria. The
135 article search and screening processes were conducted by two authors independently. The two
136 authors resolved differences by discussion. A third author was available to mediate disagreement
137 following an independent review.

138 **Data collection**

139 Data on author, study area/country, study design, sample size, crude or adjusted odds ratio (OR)
140 of death, severe illness or admission to ICU along with 95% confidence interval (CI) among
141 COVID-19 patients with comorbidities *vs* without comorbidities or different demographic status
142 were abstracted from each study. In addition, when OR was not reported, raw data was used to
143 estimate the crude ORs of death, having severe illness or admission to ICU among COVID -19
144 patients with comorbidities *vs* without comorbidities or different demographic status per study.
145 Two authors abstracted and entered data into the excel sheet independently and compared their
146 results. The final data used for analysis was approved by the two authors upon discussion.

147

148 **Quality and risk of bias**

149 The risk of bias and quality of the studies included in this review was evaluated using the
150 Effective Public Health Practice Project tool [19]. The Effective Public Health Practice Project
151 tool uses six criteria: selection bias, design, confounders, blinding, data collection, and
152 withdrawal/dropout, to examine the studies' quality. Each study's quality was determined as low,
153 moderate, and high for each of the six criteria using two items for each criterion. The study's
154 overall quality was determined as high when the study has no weak rating for each of the six
155 characteristics and moderate when the study has one weak rating in one of the six characteristics.
156 The studies were grouped as low quality when the ratings for two or more characteristics were
157 low.

158 **Data analysis**

159 Percent residual variation among studies due to heterogeneity was estimated using Moran's I-
160 squared [20]. Statistical significance of the heterogeneity was tested using the Cochran's Q chi-
161 square test [20]. The odds ratios of the studies combined in the meta-analysis to estimate the
162 summary OR were both adjusted and unadjusted estimates. A random-effect model using the Der
163 Simonian and Laird method was used to estimate the summary ORs. When heterogeneity was
164 high ($I^2 > 60\%$), subgroup analysis was performed to estimate the summary ORs after grouping
165 studies by study area/country and study design. Meta-regression was used to explore the sources
166 of heterogeneity at study-level covariates by examining the linear relationship between ORs and
167 study area/country, study design and sample size [21]. A funnel plot that displays the odds ratio
168 estimate against their standard errors was used to evaluate publication bias among the studies
169 included in the meta-analyses [22]. Statistical significance of the asymmetry of the funnel plot

170 was tested using the Egger's regression test (bias if $p < 0.1$) [23]. A 95% CI and alpha of 0.05
171 were used to assess the significance of OR.

172 **Results**

173 The initial search of articles from the databases using the keywords resulted in 4275 articles
174 (PubMed=1986, Embase= 2006, CINAHL =224, and Cochrane Library = 59) out of which 1527
175 were duplicates (Fig 1). Of the non-duplicate 2748 articles, 2444 were ineligible after screening
176 the titles and abstracts, and 233 articles were excluded after full-text review. This resulted in 71
177 articles appropriate for inclusion in the systematic review [5-10, 24-89], and 60 of them were
178 also included in the meta-analysis. The majority of the studies were conducted in China
179 (n=53), and the others from South Korea (n=2), Iran (n=1), Europe (n=6) and USA (n=9)
180 (S1 Table 3). Study designs included retrospective (n=42), cross-sectional (n=25), and
181 prospective (n=4). Clinical outcomes reported were death in 34 studies, severe illness in 45
182 studies, and admission to ICU in 11 studies. Exposure variables examined in the studies
183 included hypertension, cardiovascular disease, diabetes, chronic respiratory disease, cancer,
184 chronic kidney disease, chronic liver disease, cerebrovascular disease, smoking, age and
185 sex.

186 Fig 1. PRISMA flow diagram. Number of articles retrieved from databases, screened, excluded,
187 and included

188 **Hypertension**

189 Out of 71 studies approved for inclusion in this review, 38 examined the correlation of
190 hypertension with death, severe illness, and admission to ICU among COVID-19 patients. Out of
191 the 38 studies, 36 included in the meta-analyses. Figure 2 shows summary estimates of the odds

192 ratio of death (*vs* survival: n=13 studies), severe illness (*vs* moderate or mild: n=21 studies), and
193 admission to ICU (*vs* non-ICU: n=4 studies) among hypertensive *vs* non-hypertensive patients.
194 While some studies reported increased odds of death (n=9 studies) and severe illness (n=10
195 studies) among hypertensive patients, others reported a lack of correlation between hypertension
196 and death (n=4 studies) or severe illness (n=11 studies). A summary analysis of pooled data from
197 these studies showed moderate to high heterogeneity. Though, there were greater odds of death
198 (OR 2.60, 95% CI 1.95–3.25, $I^2 = 52.6%$, number of studies (n)= 13, number of participants
199 (N)=53,222) and severe illness (OR 1.70, 95% CI 1.30 –2.10, $I^2 = 47.8%$, n=21, N=6,172)
200 among hypertensive as compared to non-hypertensive patients. The odds of admission to ICU
201 were comparable between those who were hypertensive *vs* those who were not hypertensive (OR
202 1.20, 95% CI 0.30 –2.18, $I^2 = 79.2%$, n=5, N=1,832).

203 Fig 2. Forest plot showing the relationship of hypertension with the odds of death, severe illness
204 and admission in ICU among COVID-19 patients.

205 **Cardiovascular disease**

206 Twenty studies examined the nature of the relationship of cardiovascular disease with the odds of
207 developing death (n=7), severe illness (n=11) and admission to ICU (n=5) among COVID-19
208 patients. Out of the twenty studies, the majority showed higher odds of death (n=6) and severe
209 illness (n=8) among COVID-19 patients with cardiovascular disease (Fig 3). The remaining 1 out
210 of 7 studies showed a lack of association between cardiovascular disease and death, and 3 out of
211 11 showed a lack of association between cardiovascular disease and the odds of developing
212 severe illness among COVID-19 patients. A meta-analysis of the studies showed higher odds
213 of death (OR 5.16, 95% CI 4.10–6.22, $I^2 = 0.0%$, n=6, N=47,134), severe illness (OR 2.04, 95%

214 CI 1.01–3.08, $I^2 = 30.6\%$, $n=11$, $N=48,535$) and admission to ICU (OR 1.36, 95% CI 1.04–1.69,
215 $I^2 = 0.0\%$, $n=5$, $N=8,346$) among COVID-19 patients who had cardiovascular disease as
216 compared to those without this health problem (Fig 3).

217 Fig 3. Forest plot showing the relationship of cardiovascular disease with the odds of death,
218 severe illness and admission in ICU among COVID-19 patients.

219 **Diabetes**

220 Diabetes also is posited to be linked with the risk of developing severe illness and death among
221 COVID-19 patients. Twelve studies examined if having diabetes is correlated with the odds of
222 death among COVID-19 patients, half of which reported increased odds of death in COVID-19
223 patients with diabetes. Correlation of having diabetes with the odds of developing severe illness
224 and the odds of admission to ICU was assessed in 18 (eight reported increased odds) and five
225 (two reported increased odds) studies, respectively. A summary analysis of these studies showed
226 greater odds of death (OR 2.11, 95% CI 1.35–2.87, $I^2 = 67.4\%$, $n=12$, $N=59281$), severe illness
227 (OR 1.65, 95% CI 1.23–2.08, $I^2 = 24.9\%$, $n=18$, $N=5811$) and admission to ICU (OR 1.55, 95%
228 CI 1.20–1.90, $I^2 = 0.0\%$, $n=5$, $N=8469$) among patients with diabetes than those who had no
229 diabetes (Fig 4).

230 Fig 4. Forest plot showing the relationship of diabetes with the odds of death, severe illness and
231 admission in ICU among COVID-19 patients.

232 **Chronic respiratory disease**

233 Of 71 included studies, 19 compared the odds of death *vs* survival ($n=9$), severe *vs* moderate or
234 mild illness ($n=9$), and admission to ICU *vs* not ($n=4$) among COVID-19 patients who had

235 chronic respiratory disease *vs* those without this problem. Of the 9 studies which compared the
236 odds of death *vs* survival, six reported significantly greater odds of death among COVID-19
237 patients with chronic respiratory disease, but three documented lack of association between
238 chronic respiratory disease and the odds of death. On the other hand, out of the 9 studies which
239 compared the odds of severe *vs* mild or moderate illness among COVID-19 patients, only three
240 reported significantly greater odds of severe illness, but five showed a lack of association
241 between chronic respiratory disease and the odds of developing severe illness. One study
242 reported lower odds of severe illness among COVID-19 patients with chronic respiratory disease
243 as compared to those without chronic respiratory disease. Meta-analysis of the 19 studies showed
244 association of chronic respiratory disease with increased odds of death (OR 2.83, 95% CI 2.14–
245 3.51, $I^2 = 0.0\%$, $n=9$, $N=59,624$) and admission to ICU (OR 1.52, 95% CI 1.09–1.94, $I^2 = 0.0\%$,
246 $n=5$, $N=8,346$), but there was lack of correlation of the disease with severe illness (OR 1.39, 95%
247 CI 0.15–2.64, $I^2 = 27.0\%$, $n=9$, $N=48,381$) among COVID-19 patients (Fig 5).

248 Fig 5. Forest plot showing the relationship of chronic respiratory diseases with the odds of death,
249 severe illness and admission in ICU among COVID-19 patients.

250 **Cancer**

251 Thirteen studies examined the nature of the relationship of cancer with the odds of death ($n=5$),
252 severe illness ($n=6$) and admission to ICU ($n=3$) among COVID-19 patients. Increased odds of
253 death, severe illness and admission to ICU among COVID-19 patients who had cancer was
254 reported in 2 (out of 5), 3 (out of 6) and 1 (out of 3) studies, respectively. The remaining studies
255 showed a lack of association between having cancer and the odds of death ($n=3$), severe illness
256 ($n=3$) and admission to ICU ($n=2$) among COVID-19 patients. Meta-analysis of the 13 studies

257 showed lack of association of cancer with the odds of death (OR 1.72, 95% CI 0.39 – 3.05, $I^2 =$
258 0.0%, n=5, N=46,793), severe illness (OR 2.32, 95% CI 0.45 – 4.19, $I^2 = 0.0%$, n=6, N=3,169)
259 and admission to ICU (OR 1.79, 95% CI -0.74 – 4.31, $I^2 = 77.1%$, n=3, N=1,804) among
260 COVID-19 patients (S1 Fig).

261 **Chronic kidney disease**

262 Twelve studies examined the nature of the relationship of chronic kidney disease with the odds
263 of death (n=3), severe illness (n=7) and admission to ICU (n=2) among COVID-19 patients. Of
264 the 12 studies, two showed increased odds of death (n=1) or severe illness (n=1) among COVID-
265 19 patients who had vs didn't have chronic kidney disease. The remaining 10 studies showed a
266 lack of association of chronic kidney disease with the odds of death (n=3), severe illness (n=3)
267 and admission to ICU (n=2). Meta-analysis of the 12 studies showed lack of association of
268 chronic kidney disease with the odds of death (OR 2.32, 95% CI 0.06 – 4.58, $I^2 = 0.0%$, n=3,
269 N=4951), severe illness (OR 1.42, 95% CI 0.46 – 2.38, $I^2 = 0.0%$, n=7, N=7788) and admission
270 to ICU (OR 1.37, 95% CI 0.88–1.86, $I^2 = 0.0%$, n=2, N=6653) among COVID-19 patients (S2
271 Fig).

272 **Chronic liver disease**

273 Out of the 71 studies included in this review, only seven tested the association of chronic liver
274 disease with death or severe illness in COVID-19 patients. Of the seven studies, the only one
275 reported a correlation of chronic liver disease with COVID-19 severity. A summary analysis of
276 the seven studies showed lack of correlation of chronic liver disease with death (OR 1.41, 95%
277 CI -2.20 – 5.02, $I^2 = 0.0%$, n=2, N=352), severe illness (OR 1.35, 95% CI 0.67–2.03, $I^2 = 0.0%$,
278 n=4, N=6855) and admission to ICU (OR 1.77 95% CI 0.65 – 4.80, n=1, N=6637) (S3 Fig).

279 **Cerebrovascular diseases**

280 Six studies reported findings on the odds of death (n=2), severe illness (n=2) and admission to
281 ICU (n=2) among COVID-19 patients with cerebrovascular diseases vs those without having this
282 comorbidity. Two studies by Guan et al. 2020 [6] and Wang et al. 2020 [72] reported increased
283 odds of death among COVID-19 patients with cerebrovascular diseases. Another two studies
284 also showed association of cerebrovascular diseases with increased odds of developing severe
285 illness [37] and admission to ICU [8].

286 A meta-analysis of the two studies showed increased odds of death among COVID-19
287 patients with cerebrovascular diseases (OR 5.14, 95% CI 1.08 – 9.19, $I^2 = 0.0\%$, n=2, N=1,983),
288 but the odds of severe illness (OR 2.18, 95% CI -0.07 – 4.44, $I^2 = 0.0\%$, n=2, N=928) and
289 admission to ICU (OR 4.09, 95% CI -0.20 – 8.38, $I^2 = 0.0\%$, n=2, N=1,606) were similar
290 between patients with cerebrovascular diseases and those without this comorbidity (S4 Fig).

291 **Smoking**

292 A total of 14 studies included in the current meta-analyses that examined the impact of tobacco
293 smoking on the clinical outcomes of COVID-19. Of these 14 studies, most showed a lack of
294 association of smoking with death (2 out of 2), severe illness (9 out of 11), or admission to ICU
295 (1 out of 1) among COVID-19 patients. Only two studies showed increased odds of severe
296 illness among COVID-19 patients who were former or current smokers than non-smokers. A
297 meta-analysis of the studies showed similar odds of death (OR 0.90, 95% CI 0.70 – 1.10, $I^2 =$
298 0.0% , n=2, N=9155) or severe illness (OR 1.31, 95% CI 0.96 – 1.67, $I^2 = 0.0\%$, n=11, N=4509)
299 among COVID-19 patients who were former or current smokers than non-smokers (S5 Fig).

300

301 **Age**

302 Out of the 71 studies, 27 examined the effect of age on the odds of death, severe illness and
303 admission to ICU. Out of 27 studies, 15 treated age as >65 vs ≤ 65 years and 10 as ≥ 60 vs <60
304 years. Of the 15 studies which treated age as > 65 vs ≤ 65 years, 13 reported increased odds of
305 death (n=5) or severe illness (n=9) among patients of ages > 65 years as compared to those of \leq
306 65 years. Similarly, nine studies that treated age as ≥ 60 vs < 60 years reported increased odds of
307 death (n=6) or severe illness (n=3) among patients of ages ≥ 60 years as compared to those < 60
308 years. Chen et al. [89] also showed an increased hazard ratio of severe illness among patients of
309 Age ≥ 65 years as compared to younger individuals (Hazard ratio 3.43; 95% CI, 1.24-9.5). Dong
310 et al. [88] also reported an increased prevalence of severe COVID-19 illness in children than
311 those of adult patients. However, a study showed similar odds of severe illness among
312 individuals of ages ≥ 60 vs <60 years [80]. Two studies also reported similar odds of admission
313 to ICU among individuals of ages > 65 years vs those of ≤ 65 years [10,25]. A meta-analysis of
314 these studies showed a greater odds of death (OR 3.56, 95% CI 1.21 – 5.90, $I^2 = 18.2\%$, n=6,
315 N=13,964) and severe illness (OR 2.55, 95% CI 1.94 – 3.17, $I^2 = 24.5\%$, n=9, N=3374) among
316 patients of ages > 65 years than those of ≤ 65 years. The summary odds ratio estimates of death
317 (OR 6.09, 95% CI 3.53 – 8.66, $I^2 = 95.5\%$, n=6, N=100,733) and severe illness (OR 4.91, 95%
318 CI 1.35 – 8.47, $I^2 = 0.0\%$, n=4, N=333) among older-aged COVID-19 patients than younger ones
319 were even much greater when age was treated as ≥ 60 vs < 60 (Fig 6).

320 Fig 6. Forest plot showing the relationship of age with the odds of death, severe illness and
321 admission in ICU among COVID-19 patients.

322

323 **Gender**

324 Fifty-two studies examined the effect of gender on the odds of death (n=16), severe illness
325 (n=32) and admission to ICU among COVID-19 patients (n=6). Out of 16 studies which
326 compared the odds of death between males and females, 10 reported increased odds in males and
327 six documented similar odds between males vs female. A meta-analysis of the 16 studies showed
328 increased odds of death among males than females (OR 1.34, 95% CI 1.18 – 1.50, $I^2 = 38.7%$,
329 n=16, N=68,609). Similarly, of the 32 studies which compared the odds of severe illness
330 between males vs females, 11 reported increased odds and 21 studies document similar odds
331 between males vs female. A summary analysis of the 32 studies showed increased odds of severe
332 illness among males than females (OR 1.35, 95% CI 1.23 – 1.47, $I^2 = 0.0%$, n=32, N=13,426);
333 however, this could not be further assessed by tandem risk factors (e.g., underlying
334 cardiovascular disease) in the available data.

335 There were six studies that examined the relationship of gender with the odds of
336 admission to ICU. Out of these six studies, two showed increased odds of admission to ICU in
337 males than females, but four studies showed a lack of association between gender and the odds
338 of admission to ICU. A summary of the 6 studies showed a lack of correlation between gender
339 and admission to ICU in COVID-19 patients (OR 1.52, 95% CI 0.69 – 2.36, $I^2 = 2.9%$, n=6,
340 N=666) (Fig 7).

341 Fig 7. Forest plot showing the relationship of gender with the odds of death, severe illness and
342 admission in ICU among COVID-19 patients.

343

344

345 **Heterogeneity assessment**

346 There was no heterogeneity ($I^2 = 0.0\%$) observed among the studies included in the meta-
347 analyses that estimated the summary odds ratio of death, severe illness or admission to ICU
348 among COVID-19 patients with cerebrovascular diseases, chronic liver disease, chronic kidney
349 disease, cancer or smoker vs those without these comorbidities. There was also no or low
350 heterogeneity among the studies included in the meta-analyses that examined correlation of
351 clinical outcomes in COVID-19 patients with cardiovascular disease ($I^2 = 0.0\%$ for death and
352 admission to ICU, $I^2 = 30.6\%$ for severe illness), diabetes ($I^2 = 0.0\%$ for admission to ICU,
353 $I^2 = 24.9\%$ for severe illness), chronic respiratory disease ($I^2 = 0.0\%$ for death and admission to
354 ICU, $I^2 = 27.0\%$ for severe illness), age in years > 65 vs ≤ 65 ($I^2 = 18.2\%$ for death, $I^2 = 24.5\%$ for
355 severe illness), and gender ($I^2 = 0.0\%$ for severe illness, $I^2 = 2.9\%$ for admission to ICU,
356 $I^2 = 38.7\%$ for death). The heterogeneity level in meta-analyses performed to examine
357 associations of hypertension with the odds of death ($I^2 = 52.6\%$) and severe illness ($I^2 = 47.8\%$)
358 among COVID-19 patients was moderate.

359 However, heterogeneity was high among the studies combined in the meta-analyses to
360 examine the association of death with diabetes ($I^2 = 67.4\%$) and age, ≥ 60 vs < 60 years ($I^2 =$
361 95.5%) in COVID-19 patients. Studies that were included in the meta-analyses to assess the
362 nature of the relationship of admission to ICU with hypertension ($I^2 = 79.2\%$) also had high
363 heterogeneity. Subgroup analyses by study design dropped heterogeneity: diabetes ($I^2 = 0.0\%$ in
364 retrospective), and age ($I^2 = 0.0\%$ in retrospective; $I^2 = 0.0\%$ in cross-sectional). Due to the few
365 numbers of studies that reported results on the effect of hypertension on the risk of admission to
366 ICU, we didn't perform subgroup analyses by study region/country or study design. Removal of

367 a study by Guan et al. 2020a [6], however, significantly minimized the heterogeneity of the
368 studies that examined the effect of hypertension on the risk of admission to ICU ($I^2 = 1.0\%$).

369 On the other hand, the meta regression showed lack of effect of study area or country
370 (meta regression coefficient (β)= -0.50, $P= 0.073$), study design ($\beta = -0.23$, $P= 0.400$) and
371 sample size ($1.25e-06$, $P= 0.912$) on the log ORs of death among COVID-19 patients with
372 diabetes vs those without this problem. Similarly, study area or country ($\beta= -0.30$, $P= 0.380$),
373 study design ($\beta = \beta = -0.04$, $P= 0.863$) and sample size ($\beta = 8.74e-06$, $P= 0.631$) didn't
374 significantly predict the log ORs of admission to ICU among COVID-19 patients of age ≥ 60
375 years vs <60 years in the meta regression model.

376 **Publication bias assessment**

377 Odds ratio distributions against their standard error estimates and Egger tests for asymmetry did
378 not indicate significant publication bias: hypertension (bias 6.22, $P=0.11$), diabetes (bias 1.43,
379 $P=0.634$), cardiovascular disease (bias 1.64, $P=0.71$), chronic respiratory diseases (bias 6.47,
380 $P=0.13$), chronic kidney disease (bias 88.99, $P=0.11$), and cancer (Egger's regression test (bias) -
381 0.26, $P=0.953$) (Fig 8 and S6 Fig). Funnel plots of odds ratios of the likelihood of developing
382 severe vs moderate or mild illness among COVID-19 patients and their Egger tests also were not
383 significant: hypertension (bias 5.05, $P=0.21$); diabetes (bias 3.29, $P=0.353$), chronic respiratory
384 diseases (bias -8.36, $P=0.12$); chronic kidney disease (bias -0.57, $P=0.807$); and, cancer (bias
385 3.34, $P=0.598$) (Fig 8 and S6 Fig). Studies comparing the odds ratio of admission to ICU vs not
386 admission to ICU among COVID-19 patients with cancer (bias -6.27, $P=0.51$), hypertension
387 (bias -5.36, $P=0.12$), diabetes (bias 0.53, $P=0.763$), cardiovascular (bias 1.37, $P=0.40$), chronic
388 respiratory diseases (bias 1.98, $P=0.67$) were also spread evenly on both sides of the average OR

389 estimates, creating an approximately symmetrical funnel-shaped distribution (Fig 8 and S6 Fig).
390 The odds ratio estimates of the studies which examined the relationship of chronic liver disease
391 (bias 0.47, $P=0.752$), cerebrovascular diseases (bias -5.83, $P=0.395$) and smoking behavior (bias
392 0.98, $P=0.217$) with severe illness or death in COVID-19 patients also had approximately
393 symmetrical funnel-shaped distribution and the Egger's test for the asymmetry of the plots were
394 not significant (S6 Fig). However, there was publication bias among the studies comparing the
395 odds of i) death vs survival in patients with age > 65 vs ≤ 65 years (bias 11.29, $P=0.062$) and
396 males vs females (bias 2.90, $P=0.046$); ii) severe vs mild or moderate illness in patients with age
397 > 65 vs ≤ 65 years (bias 14.63, $P=0.032$), males vs females (bias 2.18, $P=0.039$) and those with
398 cardiovascular disease vs without having this problem (bias 5.62, $P=0.034$), the odds ratio
399 estimates scattered asymmetrically in the funnel plot (Fig 8 and S6 Fig).

400 Fig 8. Funnel plots showing the odds ratio of death, severe illness and admission in ICU against the
401 standard errors based on comorbidity and age

402 **Risk of bias and quality of the studies**

403 The study's risk of bias and quality included in this study is summarized in the supplementary
404 table (S4 table). Out of the 71 studies, 54 were moderate quality, and 18 were good quality in
405 recruiting the study participants. The majority of the studies also used good ($n=54$) or moderate
406 quality ($n=17$) reliable and valid tools to determine COVID-19 severity status and related deaths
407 among the study participants. In many studies ($n=44$), the researchers or data collectors were not
408 aware of the group (exposed vs. unexposed) to which the study participants belong in the data
409 collection process and/or the participants were blinded about the research question. About 2/3 of
410 the included studies were of moderate quality in terms of the study design (retrospective case-
411 control or cohort) and controlling confounders that may affect the relationship between

412 comorbidities and COVID-19 related outcomes or death. On the other hand, several studies rated
413 as low quality based on study design (n=15), data collection (n=8), confounders (n=26), blinding
414 (n=28) and dropouts and withdrawals (n=29). None of the studies were of low quality in terms of
415 blinding of the outcome assessor and the study participants. Total rating using the six criteria
416 showed that 14 studies were of strong quality, 23 studies were of moderate quality, and 34
417 studies were rated as low quality. Studies were included in this review, regardless of their
418 qualities.

419 **Discussion**

420 The current systematic review and meta-analysis confirmed the correlation of demographic
421 factors and comorbidities with severe illness and death among COVID-19 patients, as reported in
422 other reviews [11-13]. COVID-19 patients who were males, with age >60 or 65 years and those
423 who had hypertension, diabetes, cardiovascular disease, chronic respiratory disease and
424 cerebrovascular diseases, were found more susceptible to death. The risk of developing severe
425 illness also increased among males COVID-19 patients of ages older than 60 or 65 years, and
426 those who had hypertension, diabetes, and cardiovascular diseases. However, comorbidities,
427 including cancer, chronic kidney and chronic liver diseases, were not associated with severe
428 illness and mortality in COVID-19 patients.

429 Chronic diseases, including hypertension, diabetes, chronic respiratory disease,
430 cardiovascular disease put the body in stress for a longer period of time. This stress can weaken
431 the immune system. For example, diabetes can cause damage to β -cell through the release of
432 inflammatory cytokines such as IL-1 β and TNF α that [90]. Metabolic disorders may also impair
433 macrophage and lymphocyte function leading to low immune function [39]. Chronic disease can

434 also affect the function of different organs of the body such as the lung, heart, vascular tube.
435 These organs dysfunction and low immunity due to the chronic diseases will complicate and
436 increase the risk of severe illness and death during SARS-CoV-2 infection. It is also possible that
437 angiotensin converting enzyme inhibitors or angiotensin receptor blockers used to treat diabetes,
438 hypertension, or heart disease may upregulate Angiotensin converting enzyme 2, a receptor to
439 SARS-CoV-2 in the host cell [91-93]. This may facilitate the viral multiplication within the host
440 cell, though this is controversial [94].

441 Similarly, immunity can decrease with age, which will make older patients vulnerable to
442 develop severe illness and death during SARS-CoV-2 infection. While functional
443 immunosuppression of senescence may play a role in older adults experiencing worse disease,
444 older adults also are more likely to have an underlying chronic disease. Males may also be more
445 likely to involve in risky behaviors, including smoking, alcohol drinking and drug use, which can
446 down-regulate the immune response against the SARS-CoV-2 infection.

447 Lack of association of some chronic diseases (e.g., kidney disease) and smoking with
448 COVID-19 outcomes could be due to limitations in the original studies. The role of chronic
449 kidney disease was assessed among comparatively few participants, which could explain its
450 discordance with the results among cardiovascular equivalents. Potential ascertainment bias in
451 the original studies could also partly explain the lack of association of chronic respiratory disease
452 with severe illness though the disease showed to have a role in death and admission to ICU.
453 Similarly, lack of correlation of smoking with clinical outcomes in the COVID-19 patients could
454 be due the watering effect of the chronic disease outcomes. If most of the patients with
455 cardiopulmonary diseases were smokers, exacerbated by ascertainment bias (they did not ask
456 enough, or misinterpreted prior smoking and current smoking from never smoking), could miss

457 the distinction of tobacco use. Unfortunately, most studies didn't control chronic disease as a
458 potential confounder when examining the role of smoking on COVID-19 related outcomes.

459 These findings have a number of public health and research implications that will help in
460 the management of high-risk COVID-19 patients to mitigate the progression of the disease and
461 associated death. Based on our findings, special strategies are warranted to prevent SARS-CoV-2
462 infection and manage COVID-19 cases with underlying comorbidities, particularly older age
463 males' patients. For example, creating awareness and provision of robust personal protection
464 measures would be needed to prevent older aged individuals who have comorbidities from
465 SARS-CoV-2 infection. Second, more intensive surveillance and early hospital referral would be
466 important for older age males COVID-19 patients with comorbidities. When these high-risk
467 older age COVID-19 patients, particularly those with comorbidities, are admitted to a hospital,
468 special attention and treatment care could be considered to prevent further progression of the
469 disease and death. Third, future vaccination intervention against SARS-CoV-2 infection should
470 be formulated to better protect people with comorbidities. In addition, when the SARS-CoV-2
471 vaccination is available, people with hypertension, cardiovascular disease, diabetes, respiratory
472 system disease and cerebrovascular disease should be a priority in the vaccination
473 recommendations. The current findings also suggest prospective cohort studies with adequate
474 power to verify whether and how comorbidities and demographics can affect the risk of
475 acquisition of the SARS-CoV-2 and clinical outcomes of the disease.

476 This meta-analysis has a number of strengths. Unlike previous meta-analyses on the
477 related topic [11-13], it i) involves a comprehensive analysis of a large number of studies based
478 in China, South Korea, Iran, Europe and North America; ii) summarized the literature on the
479 effect of comorbidities, including cancer, chronic liver and cerebrovascular disease with severe

480 illness and death; and iii) compared the risk of admission to ICU vs not among hospitalized
481 COVID -19 patients stratified based on comorbidities and demographic status. In addition, we
482 found little publication bias regarding the examination of the association of comorbidities with
483 severe illness and death in COVID-19 patients. Most of our meta-analyses had no or low
484 heterogeneity, including the association of cardiovascular disease, chronic respiratory disease,
485 chronic liver, cerebrovascular disease, chronic kidney disease, age, gender and severe illness and
486 death. Although there was a high level of heterogeneity in studies that examined the correlation
487 of diabetes with severe illness, subgroup analysis by the study design significantly decreased the
488 heterogeneity. Variation in the study participant inclusion criteria and the methods used for
489 examining comorbidities among the studies could have also contributed to the observed high
490 heterogeneity.

491 However, the calculated summary OR in the current meta-analyses could have been
492 affected due to limitations in the original studies. Most studies reported frequencies or crude
493 estimates which were not adjusted for potential confounder that could affect the relationship
494 between comorbidities and the risk of severe illness or death in COVID-19 patients. In addition,
495 the sample size and/or the number of severe cases or deaths in patients with varied comorbidity
496 or demographic status were small in some studies, increasing the confidence interval estimates
497 for the OR and decreasing the power to reject false associations. These limitations in the original
498 studies could have under or overestimated the summary OR estimates of the meta-analysis that
499 examined the relationship of demographic and comorbidities with this review's outcomes.
500 Moreover, due to the cross-sectional and retrospective nature of the original studies, we cannot
501 make firm conclusions that the observed higher odds of severe illness and death among COVID-
502 19 patients were due to comorbidities, their demographic status, or other undetermined factors,

503 though this was mitigated with the incorporation of random effects. In addition, as the majority
504 of the studies included in the meta analysis were retrospective, we didn't assess the risk of
505 selection bias. Furthermore, in order to decrease the risk of misclassification bias, the exposures
506 cardiovascular diseases, diabetes and cerebrovascular diseases could be merged while examining
507 their effect on the risk of death and severe illness. However, the studies assessed and reported the
508 results for these exposures differently, separately.

509 **Conclusions**

510 In conclusion, older age and the presence of comorbidities or chronic diseases increase the risk
511 of developing severe illness, admission to ICU and death among COVID-19 patients. Special
512 strategies are warranted to prevent SARS-CoV-2 infection and manage COVID-19 cases with
513 underlying comorbidities, particularly older age male patients, though the impact in women may
514 be insufficiently observed. Prospective, longitudinal studies that control confounders are needed
515 to assess strategies for mitigating severe illness, admission to ICU, and death in COVID-19
516 patients.
