11 **Abstract**

12 In high income countries, childhood infections are on the rise, a phenomenon in part attributed  
13 to persistent hesitancy towards vaccines. To combat vaccine hesitancy, several countries  
14 recently made vaccinating children mandatory, but the effect of such vaccination laws on  
15 vaccination coverage remains debated and the long-term consequences are unknown. Here we  
16 quantified the consequences of vaccination laws on the vaccination coverage monitoring for a  
17 period of 63 years rural Finland's first vaccination campaign against the highly lethal childhood  
18 infection smallpox. We found that annual vaccination campaigns were focussed on children up  
19 to 1 year old, but that their vaccination coverage was low and declined with time until the start  
20 of the vaccination law, which stopped the declining trend and was associated with an abrupt  
21 coverage increase of 20 % to cover >80 % of all children. Our results indicate that vaccination  
22 laws had a long-term beneficial effect at increasing the vaccination coverage and will help  
23 public health practitioners to make informed decisions on how to act against vaccine hesitancy  
24 and optimise the impact of vaccination programmes.

## 26 **Introduction**

27 Infectious diseases are a major public health concern and socio-economic burden at all ages  
28 (1), but children are by far the most vulnerable to infections (2). In many low and middle-  
29 income countries, pertussis and measles remain among the top ten of all-cause mortality for  
30 children below age five (3,4). In high income countries, these infections are currently on the  
31 rise (5–11), despite the ready availability of vaccines.

32 One factor driving the increasing burden of childhood infections in high-income countries is  
33 vaccine hesitancy (5–11), i.e. partial or delayed acceptance or refusal of vaccination despite  
34 the availability of vaccines (12–14). Vaccine hesitancy is a key concern for public health  
35 institutions, because vaccination is our main tool to reduce and ultimately reach the local  
36 elimination of childhood infections (15). For the childhood infection measles and pertussis,  
37 reaching elimination requires a vaccination coverage of 95 and 98% of the population  
38 respectively (16,17), and such levels of vaccination coverage cannot be achieved with the  
39 current levels of hesitancy in high-income countries, especially for example, when there are  
40 spatial clusters of unvaccinated groups from which infections can re-emerge and spread  
41 towards other geographic regions (18).

42 One strategy to combat vaccine hesitancy is to adopt vaccination laws, i.e. make vaccination  
43 compulsory. Many states in the US and more recently in the European Union, e.g. in Italy,  
44 France and Germany in 2017, 2018 and 2020 respectively, have adopted vaccination laws  
45 which require children to be vaccinated against several childhood infections to be allowed to  
46 public schools or collective child services (19–21). These rules are enforced with fines (19,20),  
47 but children can be exempted for medical and in some states for various nonmedical reasons,  
48 which in the US resulted in a patchy vaccination coverage (22,23). Hence, to what extent  
49 vaccination laws are effective at increasing vaccination coverage is debated (24–29). So far,

50 preliminary studies and short-term monitoring indicate that recent vaccination laws have been  
51 successful at generating a short-term increase in vaccination coverage in Italy and France  
52 (19,21) and in California, where a recent vaccination policy eliminated nonmedical exemptions  
53 from school entry requirements (30). However, to what extent this is a general result and  
54 whether the increase lasts on the long-term remain unknown.

55 In this study, we quantified the vaccination coverage and the long-term impact of vaccination  
56 laws on the vaccination coverage and its spatio-temporal dynamics during Finland's first  
57 vaccination program against smallpox in the 19<sup>th</sup> century. In brief, smallpox was one of the  
58 most lethal diseases in human history, affecting especially European and Native American  
59 populations (31–33). For example, in our study population in 18<sup>th</sup> and 19<sup>th</sup> century Finland,  
60 smallpox was a major cause of death in children, killing up to 15% of Finland's population  
61 around 1800 before the introduction of vaccines (34–36).

62 Little is known on how the smallpox vaccination campaign was implemented in the 19<sup>th</sup> century  
63 and to what extent it was successful (32), especially in rural areas where vaccine uptake remains  
64 low even today in many parts of the world (37). For the purpose of this study, we digitised a  
65 series of unique historical vaccination records (63 years, 1800 pages and over 46,000  
66 individuals) maintained by the local church and the district doctor from the first vaccination  
67 campaign against smallpox in eight rural parishes of Finland (Fig. 1A, Fig. S1). This study has  
68 two aims. First, we described the seasonal and annual dynamics of the smallpox vaccination  
69 campaigns in rural Finland and which age categories were targeted. Knowing the age at  
70 vaccination is relevant for vaccine effectiveness: late vaccination diminishes protection against  
71 infection, thereby enabling the transmission of infection, while early vaccination can result in  
72 ineffective vaccination due to interference with maternal antibodies (38) in addition to  
73 considerable negative side effects (39,40). Second, we tested two hypotheses, namely: did the  
74 vaccination law cause (i) a long-term increase in *mean* vaccination coverage and (ii) a long-

75 term decrease in *variance* in vaccination coverage. Increasing vaccination coverage and  
76 stabilizing its spatio-temporal variance are important because high variance can create pockets  
77 of susceptibles from which epidemics can re-occur (41). As vaccination behaviours tend to  
78 cluster within populations, highly vaccine hesitant communities may not reach herd immunity,  
79 thus posing a risk of disease outbreak (18). The high vaccine hesitancy in the 19<sup>th</sup> century  
80 together with the rare long-term monitoring of vaccination coverage after the vaccination law  
81 provide a unique opportunity to quantify the long-term impact of vaccination laws in a high-  
82 opposition setting which is not yet possible in countries that recently implemented vaccination  
83 laws.

## 84 **Methods**

### 85 **Study population and data collection**

86 Finland's first vaccination campaign was met with high hesitancy from the public (42,43). It  
87 started in 1802, quickly after the development of world's first vaccine by the British physician  
88 Edward Jenner in 1796 (44). Historical records describe that during our observation period, the  
89 distribution of vaccines improved gradually (42,43). In 1825 the country was divided into  
90 vaccination districts, which kept record of vaccinated and non-vaccinated citizens. Each district  
91 was supervised by a district doctor, who received annual reports from the vaccinators, who  
92 were physicians, clergymen and public officers. As the opposition against vaccines remained  
93 strong despite efforts to reassure the public, a mandatory vaccination law was adopted in 1883,  
94 which required parents to vaccinate children under the age of two, which was gradually  
95 enforced in 1885-1890 and onwards with a fine (42).

96 We photographed and digitised vaccination records manually from extensive church records  
97 held in Finnish national and provincial archives. These data include details of the villagers and  
98 their lives, that were by law required to be collected by local clergymen from 1749 onwards.

99 The clergymen recorded the name, address, parents' occupation, age, and the level of success  
100 of the vaccination (as indicated by reported reaction to the vaccine: effective, mild or no  
101 reaction) for each person receiving the vaccination at a given time, as well as previously  
102 vaccinated, absent or refused individuals (Fig. S1). Based on the accessibility and completeness  
103 of historical records, we obtained data from eight rural parishes (Honkajoki, Ikaalinen,  
104 Jämijärvi, Karvia, Kustavi, Parkano, Rymättylä, Tyrvää) from 1837 until 1899, but we lacked  
105 vaccination records from 1847-1851, 1854 and 1856-1858 for all parishes excluding Ikaalinen  
106 and Tyrvää and from Kustavi before 1862 and Rymättylä before 1865 (Fig. S2 & S3). These  
107 records include information on a total of 46,232 vaccinations, 26,328 and 19,935 records from  
108 the pre-mandatory and mandatory eras respectively (Table 1).

109 In order to estimate the number of vaccinated children per age group, we gathered birth and  
110 death records for each parish from the national and provincial archives, the Genealogical  
111 Society of Finland and Finland's Family History Association digitised archives. These records  
112 consisted of yearly births and deaths per age cohort (e.g. 0-1, 1-3, 3-5), which we used to  
113 calculate the number of individuals per age cohort per parish. We estimated the vaccination  
114 coverage based on the church records and total cohort sizes by calculating the yearly proportion  
115 of vaccinated per cohort and parish from 1837 to 1899. There were a few years with >100%  
116 vaccination coverage, which are likely the result of population movement. Birth records are  
117 unlikely the cause of vaccine coverage reaching over 100% as these have been validated by  
118 independent studies (45,46). Every five to ten years we had review tables of age-specific cohort  
119 sizes per parish from the historical records which confirmed our annually estimated cohort  
120 sizes.

## 121 **Statistical analyses**

### 122 **Seasonality and age distribution of the vaccination campaign**

123 The first aim of the study is to describe the occurrence and seasonal dynamics of the vaccination  
124 campaigns. To detect whether vaccination campaigns were seasonally recurring we conducted  
125 wavelet analysis. In brief, wavelet analysis decomposes time series data using functions  
126 (wavelets) simultaneously as a function of both time (year of observation) and period, with a  
127 period of 12 months indicating a yearly seasonally recurring pattern (47). We performed all  
128 statistical analyses with the software R (version: 3.6.1 (48)). For the wavelet analyses, we fitted  
129 a Morlet wavelet with the function ‘analyze.wavelet’ of the package ‘WaveletComp’ (49). To  
130 minimize the impact of any influential data points, we smoothed and detrended the data  
131 following standard protocol (49). We determined statistical significance by comparing the  
132 observed periodicity from the data with that of 1000 ‘white noise’ simulated datasets with  
133 [95%] significance level.

134 We then describe the age structure of the vaccination campaigns. For these analyses, we used  
135 a matrix with the number of vaccinated per age group per year and divided age into four groups  
136 (0-1, 1-3, 3-5, 5+). We tested for the preference towards children under one year old using non-  
137 parametric permutation tests with the function ‘independence\_test’ of the package ‘coin’ (50)  
138 based on 10,000 permutations. We also describe the age at first vaccination for 872 individuals  
139 with exact birth dates.

#### 140 **Spatio-temporal dynamics of vaccination coverage**

141 To quantify the dynamics in vaccination coverage over time and across parishes and whether  
142 the vaccination law affected these dynamics, we used generalized linear mixed models (glms)  
143 and generalized additive mixed models (gamms). We ran four statistical models with as the  
144 dependent variable either: (a) the number of vaccinations, (b) the vaccination coverage, (c) the  
145 parish-level annual standard deviation (SD) in vaccination coverage and (d) the parish-level  
146 annual coefficient of variation (CV) in vaccination coverage (for explanation see below, Table

147 S1A-D). In all these models the predictor variable was year standardised to the mean of zero  
148 and an SD of one.

149 We fitted glms with the functions ‘glm’, ‘lme’ and ‘gls’ respectively of the packages ‘stats’  
150 (32) and ‘nlme’ (51). These gave consistent results and we here present the results using ‘glm’  
151 for the number of vaccinated (Poisson distributed counts; model (a)), ‘lme’ for vaccination  
152 coverage (Gaussian distributed; model (b)) and ‘gls’ for parish-level SD and CV (Gaussian  
153 distributed with temporal autocorrelation, see below, models (c) and (d)). To quantify the  
154 statistical ‘significance’ of predictor variables, we compared the model fits on the data with the  
155 second order Akaike Information Criterion (AICc; (52,53)), using the function ‘AICc’ of the  
156 package ‘MuMIn’ (54). In brief, model selection ranks the models based on their AICc value,  
157 where better fitting models are indicated by lower AICc, models within 4  $\Delta$ AICc are considered  
158 plausible, and increasingly implausible up to 14  $\Delta$ AICc after which they are implausible  
159 (52,53).

160 To account for the fact that people are clustered into parishes, we included parish identity as a  
161 random intercept in model (b), the vaccination coverage analyses, which improved the model  
162 fit ( $\Delta$ AICc=-29 in Table S1B). To have an idea of the importance of parish level differences,  
163 we reported the proportion of variance in the model explained by the random intercept and  
164 estimated the repeatability of parish-level differences with the function ‘rpt’ of the package  
165 ‘rptR’ (55). The repeatability is an intra-class correlation coefficient that captures the between-  
166 parish variance (by parish identity as a random intercept) relative to the total variance and  
167 ranges from zero (no parish-level differences) to one (all variance in the dependent variable is  
168 explained by parish-level differences). We estimated the 95% confidence intervals (95CI)  
169 around the repeatability based on 1000 bootstraps.

170 All model residuals were correctly distributed and fulfilled all other assumptions as checked  
171 with the function 'simulateResiduals' of the package 'DHARMA' (56). In model (b), there was  
172 however heteroscedasticity as identified with the functions (i) 'testQuantiles' from the package  
173 'DHARMA' (56), and (ii) the Breusch-Pagan test performing a linear model using as dependent  
174 variable the squared value of the conditional residuals of the model (b) and standardised year  
175 as predictor variable (57). In model (b), we corrected for heteroscedasticity by including the  
176 variance power ('varPower') in the function 'weights' (58,59). We then tried to identify two  
177 sources of changes in heteroscedasticity by decomposing vaccination coverage into a parish-  
178 level component and an annual component. For the parish-level component, we used as the  
179 dependent variable the annual parish-level SD and CV in vaccination coverage (respectively  
180 models (c) and (d), Table S1 C & D). To identify whether there was an annual component in  
181 heteroscedasticity we used the Breusch-Pagan test as described above on the annual mean in  
182 vaccination coverage (excluding parish-level variance) and using pre-mandatory and  
183 mandatory era as a two-level categorical predictor.

184 We controlled for temporal autocorrelation following (60) by including standardised year as  
185 an auto-regressive factor of order 1 (corAR1). In models (a) number of vaccinated and (b)  
186 vaccination coverage, this worsened the model fit ( $\phi=0.57\pm 0.25$ ,  $\Delta AIC_c=+155$  for model b in  
187 Table S1B), indicating no temporal autocorrelation, a conclusion also supported with the  
188 function 'acf' (ACF<0.1) of the package 'stats' (32). For these models, we hence presented the  
189 results without temporal autocorrelation, but analyses including temporal autocorrelation gave  
190 consistent conclusions (results not shown). Models (c) and (d), respectively parish-level SD  
191 and CV in vaccination coverage were autocorrelated and thus we included the corAR1  
192 autocorrelation structure in these models.

193 To investigate whether there were abrupt changes in vaccination coverage or its spatio-  
194 temporal variance which coincided with the start of the vaccination law, we fitted threshold

195 models following Douhard et al. (61) and Briga et al (62). In brief, for each model (a-d), we  
196 tested a series of threshold models, with one year interval between each threshold and identified  
197 the best fitting threshold model based on the model's AICc value. To identify whether threshold  
198 models were appropriate at all, we compared the model fit of the best fitting threshold model  
199 with that of a linear model without threshold (Table S1 A-D). We identified the confidence  
200 interval around the threshold year by including all models within 4  $\Delta$ AICc of the best fitting  
201 threshold model (61,62), abbreviated as 4AICCI (Fig. S4 A, B, C & D). To confirm the results  
202 of threshold models, we performed all analyses also using generalized additive mixed models  
203 (gamms), with the function 'gamm' of the package 'mgcv', and to identify the year of change  
204 (inflection points) we used their derivatives with the function 'fderiv' of the package 'gratia'  
205 (63). All gamm analyses confirmed the conclusions obtained from the threshold models (Fig.  
206 S5 A-H).

207

## 208 **Results**

### 209 **Seasonality and age distribution of the vaccination campaign**

210 Here we present data covering eight rural parishes in South-West Finland (Fig. 1A), with  
211 26,328 records (57%) during the 46 years of the pre-mandatory era from 1837 to 1882 (average  
212 572 records per year) and 19,935 records (43%) during the 17 years of mandatory era from  
213 1883 until 1899 (average 1173 records per year; Table 1).

214 During both eras, vaccination campaigns started in May or June, occurred predominantly in  
215 summer and often ended in August or September (Fig. 1B). This seasonal pattern was  
216 confirmed by wavelet analysis, where we observed a statistically significant annual vaccination  
217 periodicity ( $p < 0.05$ ), both on average over the whole observation period ( $p < 0.05$ , Fig. S2A)  
218 and in the time dependent analyses ( $p < 0.05$ , Fig. S2B).

219 We then investigated the age distribution of the people vaccinated during the campaigns. There  
220 was a clear preference towards children under age one, with in the pre-mandatory era on  
221 average 69% of the records being under age one, 21% between one and three years, 5.3%  
222 between three and five years and 4.5% five years old or older ( $\chi^2= 1143$ ,  $p<0.0001$ , Fig. 2A).  
223 In the mandatory era, the preference towards one-year olds was 10% higher at 80% of the  
224 records and this increase was statistically significant ( $\chi^2= 39.73$ ,  $p=2.9e-10$ , Fig. 2A). We did  
225 not observe a lower limit for the age at first vaccination (Fig. 2B): 872 of the 34,496 records  
226 (2.5%) of the children under the age of one were below the age of 3 months. Thus, there was a  
227 preference to vaccinate before age one which increased with time and with no apparent lower  
228 age limit.

### 229 **Spatio-temporal dynamics of vaccination coverage**

230 The number of vaccinations increased with time (Fig. 2A, Table S1A). Threshold models  
231 showed that this increase accelerated after the break point in 1871 ( $1871<4AICCI<1871$ ; Fig.  
232 S4A) and this result was supported by gamm models (Fig. S5A&B). This break point coincided  
233 shortly after the drop in births during the famine years 1867-68. Because vaccination dynamics  
234 can be driven mostly by the dynamics of births (Fig. 2A), we studied birth-independent  
235 spatiotemporal dynamics of vaccinations by using vaccination coverage, i.e. the number of  
236 individuals vaccinated relative to the number of individuals in the age category and focused  
237 the analyses below on children until age one year.

238 We tested the hypothesis that the vaccination law increased the vaccination coverage. In the  
239 pre-mandatory era, the vaccination coverage was on average 68% (SD=27.8,  
240  $18.7<[95CI]<147$ ) and in the mandatory era this increased with 20% to 88% (SD=21.5,  
241  $57.4<[95CI]<143$ ; Fig. 3). Analysing these time series with threshold models showed an abrupt  
242 increase in vaccination coverage in 1882 ( $1882<4AICCI<1882$ ;  $\Delta AICc$  relative to a linear

243 increase=-30.4; Table S1B; Fig. 4, Fig S4B). Before the threshold the vaccination coverage  
244 decreased with time, while after the threshold we observed an increase. Before the threshold,  
245 the 95CI of coefficient does not overlap with zero and hence is statistically significant, but after  
246 the threshold the 95CI overlaps with zero and hence is not significant (respectively:  $\beta_1=-4.27$ ,  
247  $-8.35<[95CI]<-0.20$ ,  $p=0.04$ ;  $\beta_2=9.22$ ,  $-6.89<[95CI]<25.33$ ; Table S1B). Gamm models  
248 supported the conclusions of threshold models with the gam derivative indicating the steepest  
249 increase in coverage in 1882 (Fig. S5C&D). Hence, the implementation of the vaccination law  
250 was associated with (i) a stop in declining coverage and (ii) an abrupt 20% increase in coverage  
251 which (iii) persistent on the long-term.

252 We then tested whether the variance in vaccination coverage changed over time and Breusch-  
253 Pagan test indicated a decrease in variance ( $\Delta AICc=-15.49$ ). We tried to decompose whether  
254 this decrease in variance is due to a spatial (between parishes) and/or a temporal (between  
255 years) component. Vaccination coverage varied substantially and consistently between  
256 parishes: parish identity captured 9.0% of the variance in vaccination coverage during the pre-  
257 mandatory era which increased to 46% in the mandatory era (model in Table S1B) with a  
258 repeatability of respectively 0.083 ( $0.00<[95CI]<0.21$ ) and 0.32 ( $0.069<[95CI]<0.55$ ). The  
259 parish-level SD and CV in vaccination coverage decreased over time and showed an abrupt  
260 change around 1873 (SD:  $1869<4AICCI<1876$ , CV:  $1872<4AICCI<1874$ ; Table S1C & S1D;  
261 Fig. 3B, Fig. S4C&D) and gamm models confirmed these conclusions (Fig. S5E-H). The  
262 interannual SD decreased as well with time, from 12.94 in the pre-mandatory era to 6.48 in the  
263 mandatory era (Breusch-Pagan test  $p=0.46$ ). Hence the variance in vaccination coverage  
264 stabilized between parishes and over time, but the parish-level stabilization started  
265 approximately ten years before the introduction of the vaccination law.

266

## 267 **Discussion**

268 Commonly preventable childhood infections are on the rise in many contemporary high-  
269 income countries following decreases in vaccination coverage, which has led to vaccination  
270 laws against infections such as measles and pertussis e.g. in Europe, many US states and  
271 Australia. However, we know almost nothing on the long-term effects of vaccination laws on  
272 vaccination coverage and its dynamics. In this study, we show that the Finland's first  
273 vaccination campaigns in rural parishes were mainly executed during the summer, often in the  
274 middle of farming season and most of the vaccinated individuals were under the age of one  
275 year. We show an abrupt increase in vaccination coverage which coincided with the start of a  
276 vaccination law and persisted for at least 15 years. However, we also found differences in  
277 vaccination coverage between parishes, and although spatio-temporal variance in vaccination  
278 coverage decreased with time, this variance persisted and its sudden decrease ten years before  
279 the vaccination law appeared not to be associated with the vaccination law. Here we discuss  
280 three implications of our results for the impact of vaccination campaigns and vaccination  
281 policy.

282 First, low vaccination coverage in rural areas is a challenge that contemporary vaccination  
283 campaigns try to solve, especially in low and middle income countries (64–66). Increasing the  
284 vaccination coverage in these areas is important because spatial heterogeneity in vaccination  
285 coverage creates low vaccination clusters which can become a source of outbreaks that spread  
286 towards other areas (18). Our finding of repeatable parish-specific vaccination coverage show  
287 that vaccination coverage is a geographically local characteristic. The reasons behind the poor  
288 and fluctuating coverage in rural communities are complex (12,64,65), but at least two  
289 possibilities stand out. Firstly, remote parishes are often more difficult to access and possibly  
290 less well managed than more urban parishes (67). Secondly, people living in remote rural  
291 parishes might be less motivated or more hesitant to vaccinate (68,69). We observed a decline

292 in the spatio-temporal variation in vaccination coverage, indicating improvements in the  
293 management of the vaccination campaign and reduction in inequity between the parishes.  
294 Although vaccination law probably attributed to this decline, it started a decade earlier and  
295 shortly after the famine years (1867-68), which suggests that it is not directly associated with  
296 the vaccination law itself and is for example more likely due to improved accessibility in certain  
297 rural areas.

298 Second, one notable characteristic of the campaign was that children seemed to be vaccinated  
299 without lower age limit. Smallpox epidemics were still prevalent during the 19<sup>th</sup> century and  
300 as vaccinators travelled to rural areas only once a year, early vaccination may have been the  
301 optimal solution at the time. However, we now know that early vaccination can be ineffective,  
302 for example through maternal blunting, where maternal antibodies of vaccinated mothers  
303 interfere with infant immune response and lower the infant's responsiveness to vaccines (38),  
304 hence for example in contemporary societies a recommended age at first vaccination of at least  
305 three months for several childhood infections and one year for smallpox (39).

306 Finally, mandatory vaccinations have been one of the strategies considered to combat low  
307 vaccination coverage, but this approach has always been controversial and associated with  
308 opposition (70). Our results show an abrupt increase in the vaccination coverage at the start of  
309 the vaccination law. Similarly, short-term studies in contemporary societies observed  
310 immediate increases in vaccination coverage after the introduction of the vaccination laws  
311 (19,71) and our study suggested that the observed increases will persist on a longer term.  
312 Moreover, there were no major lethal smallpox outbreaks after 1882 (Fig. S6), reflecting that  
313 vaccination together with for example the general improvements in living conditions (72)  
314 diminished the lethal burden of smallpox.

315 Our study has several limitations. First, instead of vaccine hesitancy, vaccine delivery can be a  
316 major factor affecting vaccination coverage (73). In our study population, vaccine uptake likely  
317 improved at least in part due to better distribution and managing of the vaccination campaign.  
318 We cannot exclude sudden organisational changes of vaccination campaigns, but historical  
319 records indicate organisation improved gradually during our observation period (42,43). This  
320 is also indicated by the changes in CV and SD in vaccination coverage which occurred 10 years  
321 prior to the vaccination law, which probably reflects an improvement in Finland's access to  
322 vaccines. Thus, in our study, the vaccination law and associated fines constitute just one factor  
323 that increased the vaccination coverage. Second, our study population was limited to eight rural  
324 towns from western-Finland. As vaccination campaigns may differ between cities or rural  
325 parishes, it is unclear to what extent we can extrapolate the characteristics of the vaccination  
326 campaign and the response to the vaccination law in time and space. Third, as parishes did not  
327 decline anybody wanting to get vaccinated, our estimates for the number of vaccinated also  
328 include temporary travellers from other parishes, which results in some data points with >100%  
329 vaccination coverage, indicating an overestimation of the vaccination coverage of the locals.  
330 Thus, vaccination campaigns were probably not quite as successful before or after the  
331 vaccination law as our estimates indicate.

332 The reasons behind changes in vaccine uptake remain complex and hence other measures than  
333 vaccination laws, such as training medical professionals about vaccines, actively  
334 recommending vaccines and good communication with the lay public are also needed to  
335 increase the vaccination coverage (29,74). Implementing vaccination laws with clear and  
336 consistent communication can help reach infection-specific thresholds for herd immunity and  
337 subsequent elimination (41,75). Our study indicates that vaccination laws will be an effective  
338 long-term tool in the public health battle to increase vaccination coverage and towards the

339 elimination of childhood infections, even in socio-demographic contexts (rural areas, pre-  
340 health care periods) where vaccines are often met with higher reluctance than in urban areas.

341

## 342 **Acknowledgements**

343 Many thanks to Kimmo Pokkinen, Sara Itkonen and Tuija Koivisto for help with historical  
344 data, to the National Archives of Finland for allowing us to digitize and use the vaccination  
345 records and to Finland's Family History Association and the Genealogical Society of Finland  
346 for access to the birth and death data. We are grateful to the Nordemics Consortium for useful  
347 discussions. For funding, we thank the valuable contributions from the Doctoral Programme in  
348 Biology, Geography and Geology, University of Turku, the Ella & Georg Ehrnrooth  
349 Foundation, the Academy of Finland (292368), ERC (CoG 648766) and NordForsk (104910).  
350 The authors declare no conflicts of interest. The data supporting the findings of our study are  
351 derived from three public domains: the National Archives of Finland, Finland's Family History  
352 Association and the Genealogical Society of Finland.

## Figures and tables

583 Table 1. Overview of the data, where we describe year, population and sample size, average number of vaccinated  
 584 per year per parish, average timing and vaccination coverage per age category and interannual and interparish  
 585 standard deviation (SD) and coefficient of variation (CV) of vaccination coverage for both pre-mandatory and  
 586 mandatory eras. Children were grouped into the following age categories: under 1 year old (age <1) and between  
 587 1 and 5 years (from age 1 year until 5 years).

	<b>Pre-mandatory era</b>	<b>Mandatory era</b>
Years	1837-1882	1883-1899
Average population size per parish	2600	3700
N vaccinated	26328	19935
Average n vaccinated per year per parish	108	148
Average [95CI] vaccination month	7.40 ± 0.018 (mid-July)	6.72 ± 0.011 (late June)
Average % of vaccinated under 1 year old	68.1	87.5
Average % vaccinated between 1 and 5 years	16.3	10.3
Interannual and -parish SD of vaccination coverage	27.8	21.5
Interannual and -parish CV of vaccination coverage	40.9	24.6

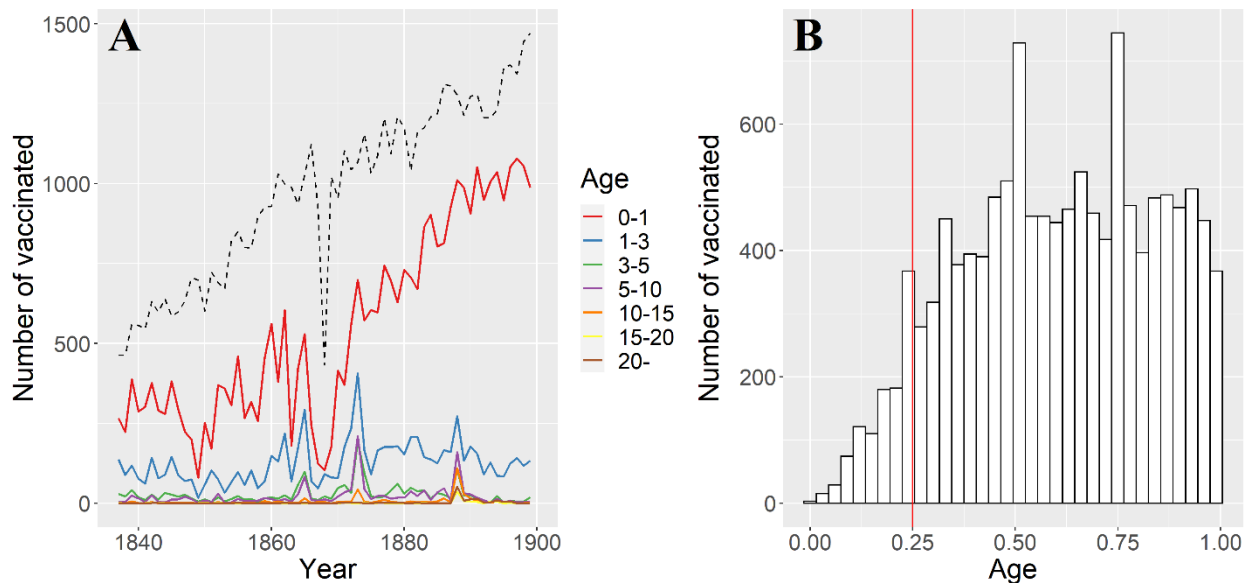

588

589

590 Figure 1. Geographical and temporal distributions of the data, showing (A) map of the eight rural parishes in  
 591 south-west Finland with a map of Northern Europe on the left and a zoomed-in map of south-west Finland on the  
 592 right, and (B) the predominant seasonal timing of annual vaccination campaigns occurring in summer.

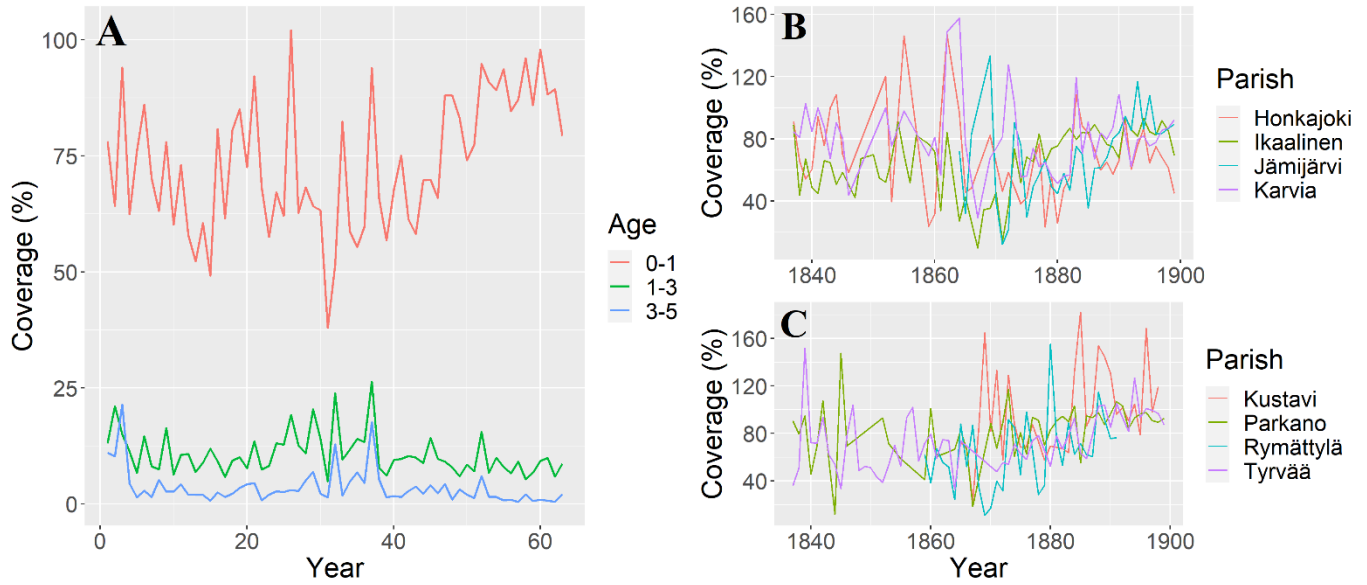

593

594

595 Figure 2. Smallpox vaccinations had a preference towards the youngest age groups (A) with no apparent minimum  
 596 age (B). The number of vaccinated per age group (A) and age distribution for children under the age of one year  
 597 (B). The dashed black line in (A) indicates the number of annual births in the eight study parishes. The red line in  
 598 (B) indicates contemporary recommendation for age at first vaccination, which is 3 months in Finland for most  
 599 vaccines. For smallpox, the recommended age at first vaccination is one year (39).

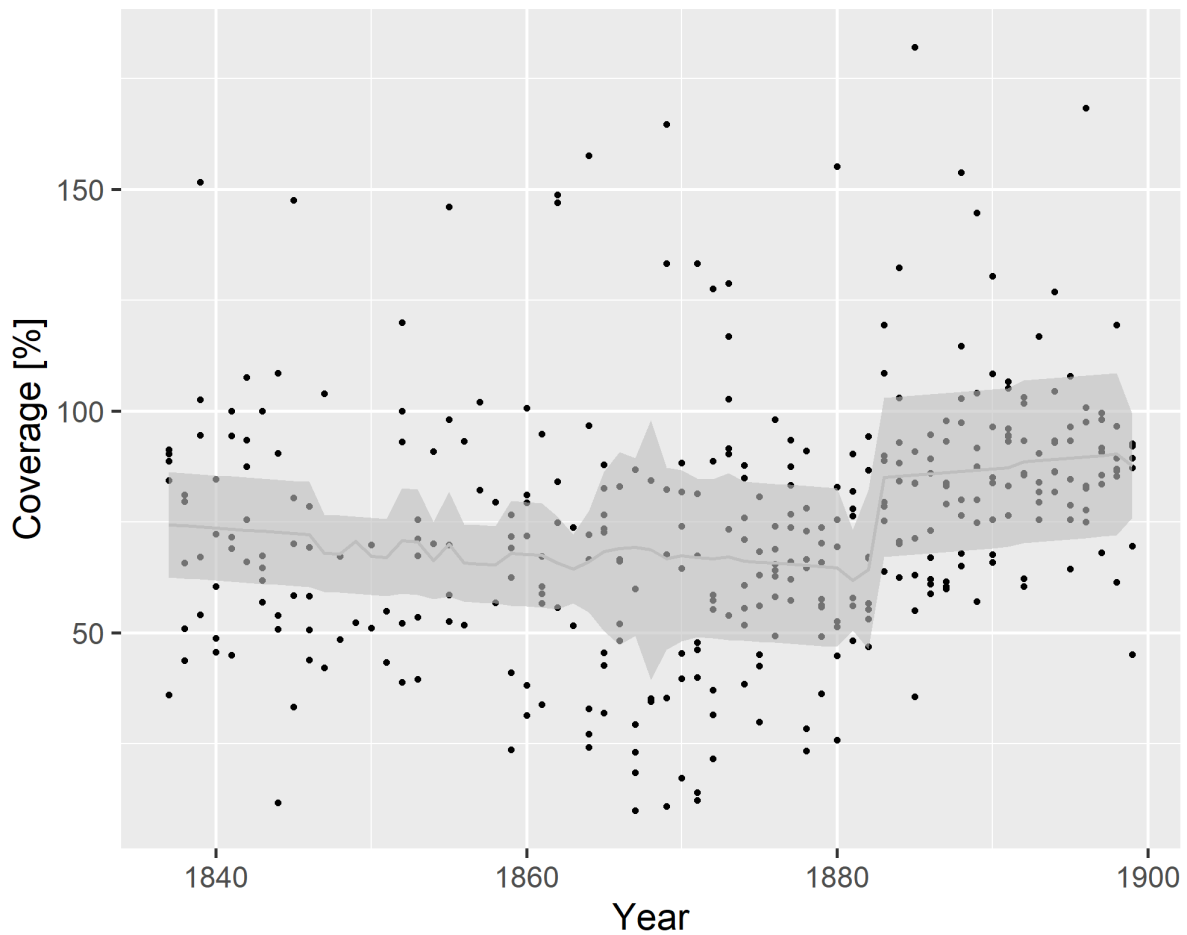

600

601

602 Figure 3. The vaccination coverage increased after the introduction of vaccination law in 1883 (A) together with

603 the decrease in the variance between parishes, which, for illustrative purposes, are shown in two plots (B-C).

604

605 Figure 4. The temporal dynamics in vaccination coverage of children until age one year are best captured by a

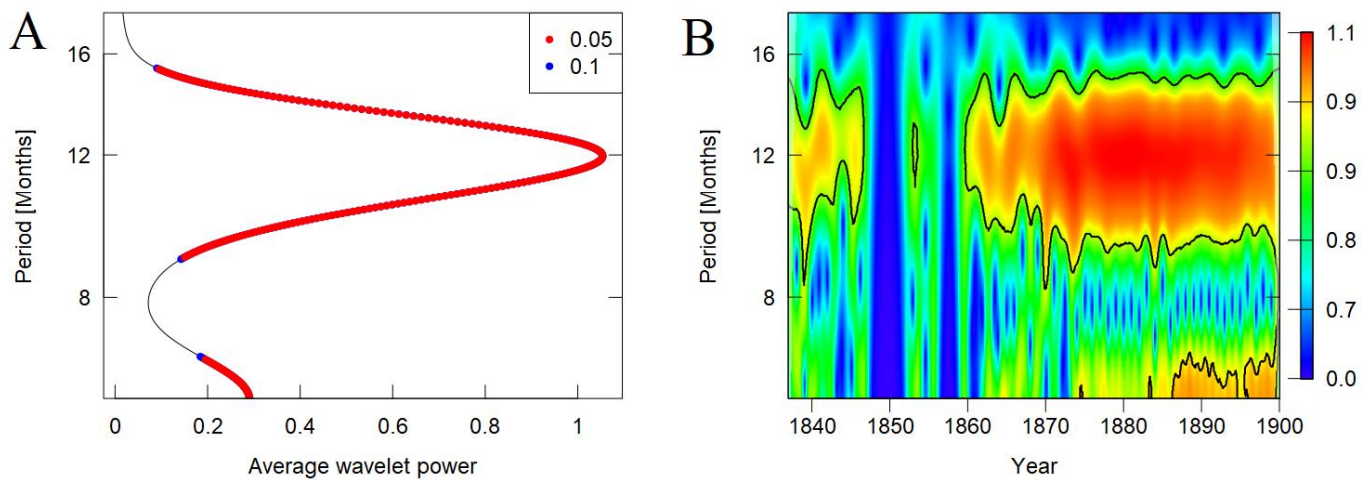

606 threshold model with an increase in vaccination coverage after 1882. Before the threshold, the vaccination

607 coverage decreases with time, while after the threshold there is an increase but the 95% CI of both coefficients  
608 overlap with zero and hence are not statistically significant. The predicted values are plotted as a light grey line  
609 against the black observed datapoints and the grey bands represent the [95%] confidence intervals.

610

611

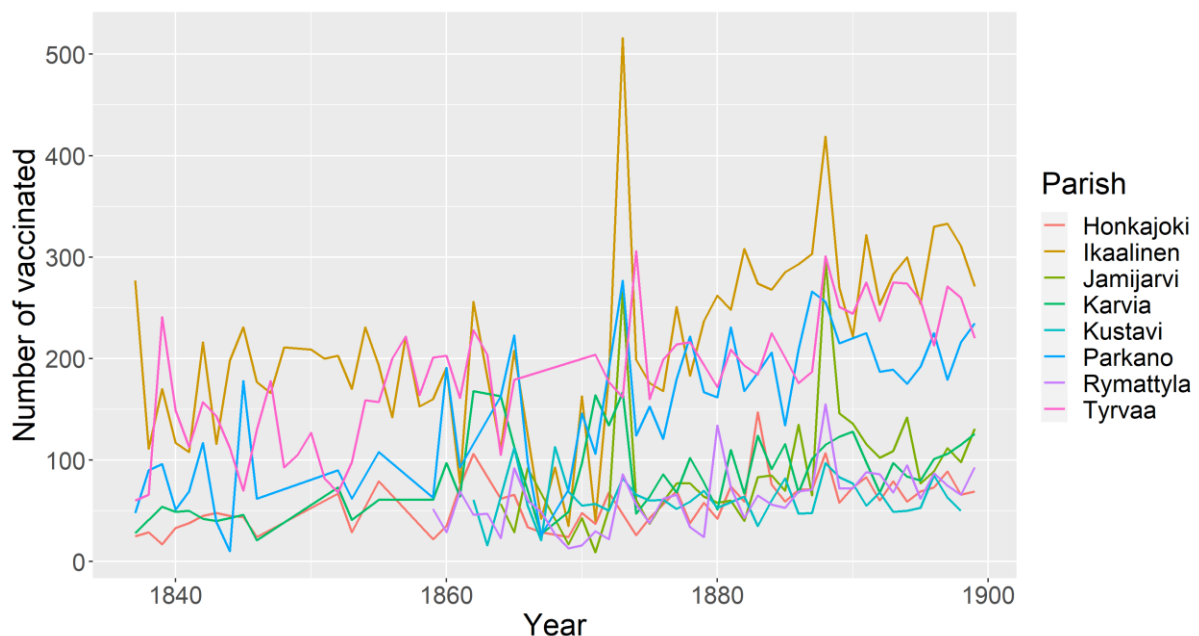

624

625 Figure S2. Wavelet periodogram (A) and wavelet power spectrum (B) for season at vaccination show a consistent  
626 average around one year from 1837 until 1899. A) A smaller peak can be observed at 6 months. Red dots represent  
627 significance at the 5% level and blue dots 10% level. The axis describe period in months on the y-axis and wavelet  
628 power levels on the x-axis. B) Legend describes wavelet power levels, where red indicates strong periodicity and  
629 green to blue signals weak periodicity. The blue gaps around 1850-1860 represent a gap in the data from all  
630 parishes at that time. The black line highlights the one-year mark in both plots.

631

632

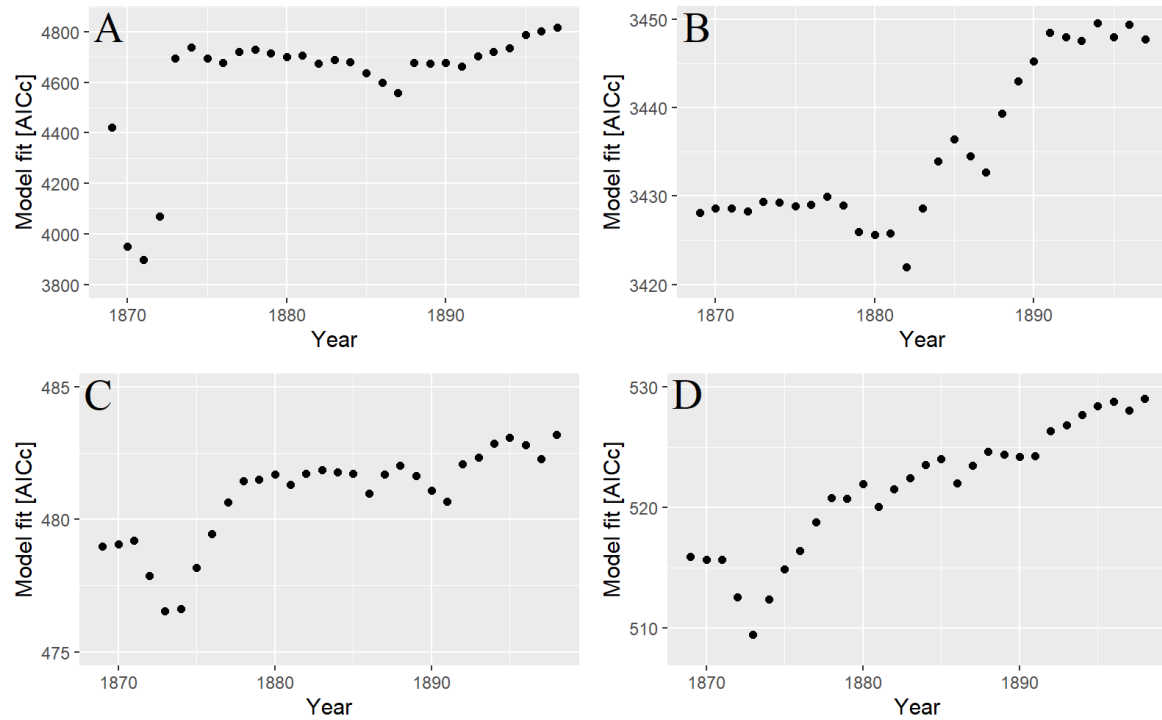

633 Figure S3. The number of vaccinated individuals increased towards the end of the 19<sup>th</sup> century as monitored from  
634 1837 to 1899.

635

636 Table S1. The model selection table indicated a quadratic increase in the number of vaccinated (count),  
637 vaccination coverage and coefficient of variation over time, but was not a significant predictor in standard  
638 deviation models. The table describes model type, model intercept, threshold intercept (Intercept2), scaled year  
639 coefficient, scaled threshold year coefficient (year2), period (before vs. after the law), model AICc, delta AICc,  
640 Akaike weight and threshold year for each dependent variable. The vaccination coverage model in B includes  
641 parish as a random variable. Best fitting models are indicated in italic.

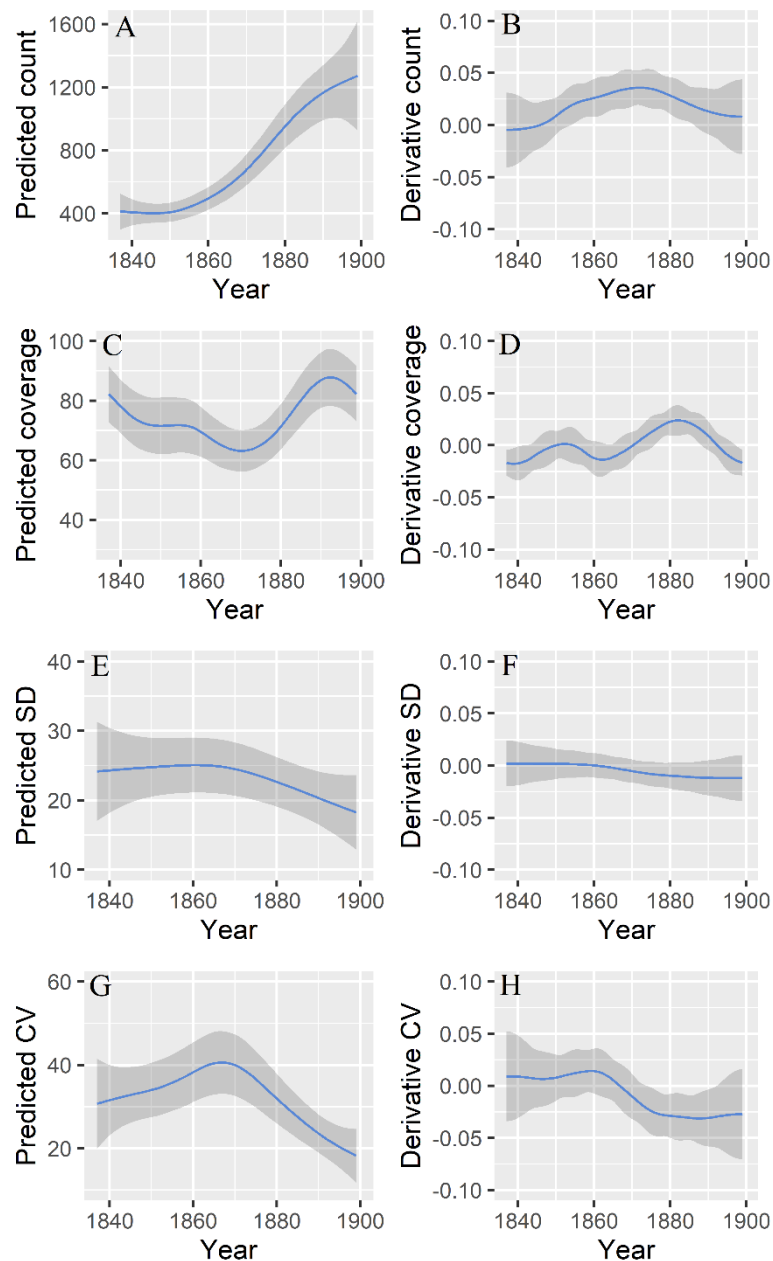

Model	Model output				Model selection			
	Intercept	Intercept2	year	year2	AICc	ΔAICc	weight	threshold
A) Vaccination count								
Linear	6.51		0.43		4892.08	995.02	0.00	
No year-related change	6.60				12781.81	8884.75	0.00	
<i>Threshold</i>	<i>6.22</i>	<i>0.60</i>	<i>0.14</i>	<i>0.041</i>	<i>3897.06</i>	<i>0.00</i>	<i>1.00</i>	<i>1871</i>
B) Vaccination coverage								
Linear	63.33		8.21		3525.57	48.84	0.00	
No year-related change	62.82				3552.65	75.91	0.00	
<i>Threshold</i>	<i>54.13</i>	<i>21.21</i>	<i>-3.02</i>	<i>10.45</i>	<i>3476.73</i>	<i>0.00</i>	<i>1.00</i>	<i>1882</i>
C) Parish-level standard deviation in vaccination coverage								
Linear	23.29		-1.70		475.92	12.22	0.00	
No year-related change	23.26				477.60	13.90	0.00	
<i>Threshold</i>	<i>29.98</i>	<i>-8.73</i>	<i>5.56</i>	<i>-7.05</i>	<i>463.70</i>	<i>0.00</i>	<i>1.00</i>	<i>1873</i>
D) Parish-level coefficient of variation in vaccination coverage								
Linear	32.49		-3.74		520.38	30.13	0.00	
No year-related change	32.43				524.63	25.88	0.00	
<i>Threshold</i>	<i>48.09</i>	<i>-15.70</i>	<i>13.57</i>	<i>-21.17</i>	<i>494.50</i>	<i>0.00</i>	<i>1.00</i>	<i>1873</i>

642

643

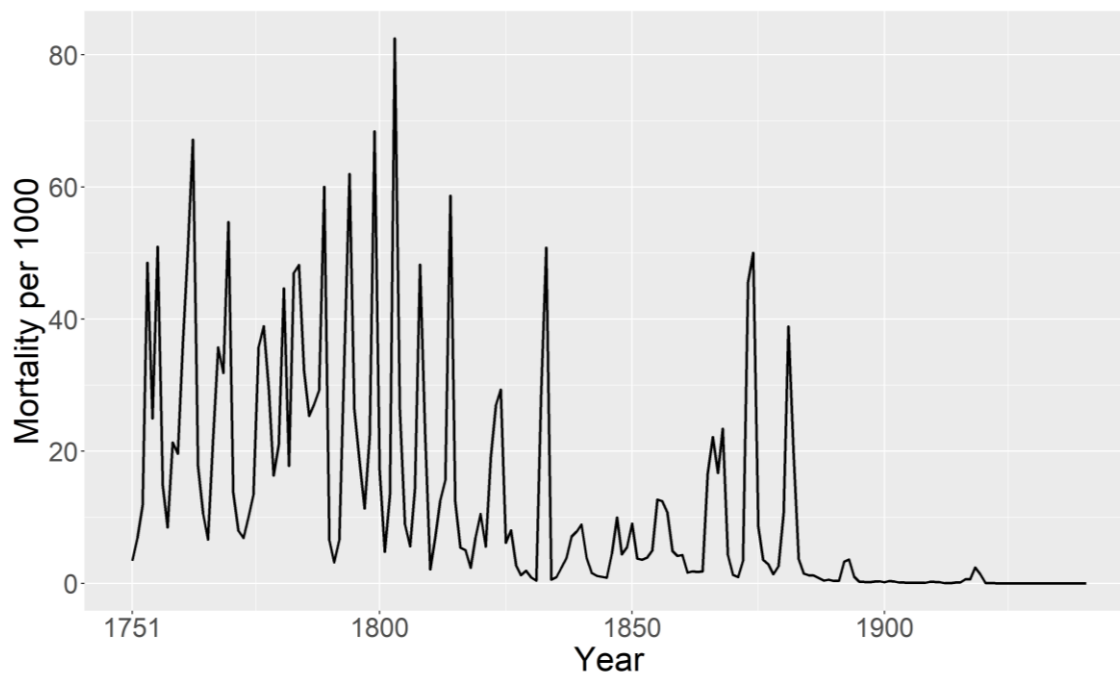

644 Figure S4. The number of vaccinated showed statistically significant threshold in 1871 (A, Table S1A), while the  
645 vaccination coverage showed a statistically significant threshold in 1882 (B, Table S1B). Both parish-level SD  
646 and CV models showed a statistically significant threshold in 1873 (C&D, Table S1C&D).

647

648 Figure S5. Gamm models show the steepest increase for number of vaccinated in 1871 (A) and vaccination  
649 coverage in 1882 (C), and for both parish-specific SD and CV a decrease starting from 1873 onwards (E&G).  
650 Shown here are the predicted values (A, C, E, G) and the derivatives of the GAMM models (B, D, F, H) for  
651 vaccination count (eq. model Table S1A; A&B), vaccination coverage (eq. model Table S1B; C&D) and parish-  
652 specific SD (eq. model table S1C; E&F) and parish-specific CV (eq. model Table S1D; G&H). Vaccination  
653 coverage models included parish identity as a random factor. All models used autocorrelation structure AR1 for  
654 year and estimated 95% confidence intervals (grey band) around the predicted slopes (blue line).

655

656 Figure S6. Smallpox mortality in Finland from 1751 to 1940. Original data from Pitkänen, Mielke & Jorde 1989  
657 (Appendix Table 1).
