ABSTRACT

Background

While diagnostic, therapeutic, and vaccine development in the COVID-19 pandemic has proceeded at unprecedented speed and scale, critical gaps remain in our understanding of the immune response to SARS-CoV-2. Current diagnostic strategies, including serology, have numerous limitations in addressing these gaps. Here we describe clinical performance of T-Detect™ COVID, the first reported assay to determine recent or prior SARS-CoV-2 infection

based on T-cell receptor (TCR) sequencing and immune repertoire profiling from whole blood samples.

Methods

Methods for high-throughput immunosequencing of the TCR β gene from blood specimens have been described¹. We developed a statistical classifier showing high specificity for identifying prior SARS-CoV-2 infection², utilizing >4,000 SARS-CoV-2-associated TCR sequences from 784 cases and 2,447 controls across 5 independent cohorts. The T-Detect COVID Assay comprises immunosequencing and classifier application to yield a qualitative positive or negative result. Several retrospective and prospective cohorts were enrolled to assess assay performance including primary and secondary Positive Percent Agreement (PPA; N=205, N=77); primary and secondary Negative Percent Agreement (NPA; N=87, N=79); PPA compared to serology (N=55); and pathogen cross-reactivity (N=38).

Results

T-Detect COVID demonstrated high PPA in subjects with prior PCR-confirmed SARS-CoV-2 infection (97.1% 15+ days from diagnosis; 94.5% 15+ days from symptom onset), high NPA (~100%) in presumed or confirmed SARS-CoV-2 negative cases, equivalent or higher PPA than two commercial EUA serology tests, and no evidence of pathogen cross-reactivity.

Conclusion

T-Detect COVID is a novel T-cell immunosequencing assay demonstrating high clinical performance to identify recent or prior SARS-CoV-2 infection from standard blood samples. This assay can provide critical insights on the SARS-CoV-2 immune response, with potential implications for clinical management, risk stratification, surveillance, assessing protective immunity, and understanding long-term sequelae.

INTRODUCTION

The emergence and rapid spread of SARS-CoV-2, the virus that causes coronavirus disease (COVID-19), has resulted in a global pandemic of over 75 million cases and 1.7 million deaths worldwide in 2020³. Despite rapidly accumulating data and recent approvals of vaccines, key gaps remain in our understanding of the immune response to SARS-CoV-2, including the nature and durability of the correlates of protection, the relationship between immune response and individual disease susceptibility and severity, and the possibility that some immune phenotypes may be more advantageous or efficient at preventing infection or severe disease⁴⁻⁶.

Such knowledge gaps translate into critical areas of unmet need in the diagnosis and management of COVID-19 and epidemiologic monitoring of the pandemic. Currently, serologic (antibody) testing of IgM, IgG, and/or IgA isotypes is the primary modality for evaluating prior SARS-CoV-2 infection or exposure, disease prevalence and incidence, and immune protection⁷⁻⁹. While antibody testing has been shown to capture a larger percentage of exposures than PCR testing¹⁰, its performance has a number of limitations, including low or absent antibody titers in individuals with asymptomatic or mild infection^{11,12}, declines in antibody levels over time^{13,14}, and false-positive results from cross-reactivity to other viruses, infections, or unrelated autoimmune conditions¹⁵⁻¹⁷. There is also wide variability in performance across the numerous SARS-CoV-2 serologic tests currently available¹⁸. In addition, it remains unclear whether the results of antibody testing correlate with long-term protective immunity or prevention of transmission⁹. Finally, serologic testing may not reflect the true extent of individual pre-existing immunity, as SARS-CoV-2-reactive T-cells have been identified in 20-50% of individuals with no known exposure¹⁹⁻²¹. These issues have severely limited the utility of serologic testing to

inform individual risk or guidance of public behavior, including physical distancing, mask wearing or resumption of activities²².

Recent reports showing declining levels of anti-SARS-CoV-2 IgG and neutralizing antibodies only a few months after infection, particularly in asymptomatic individuals, have fueled concerns that achieving long-term immunity to SARS-CoV-2, whether by natural infection or by vaccination, will be challenging^{11,13,14}. This is supported by accumulating data regarding SARS-CoV-2 reinfections in as few as 2 months following initial infection^{23,24}. The observation that pan-Ig antibody titers appear stable up to 4 months following diagnosis suggests that long-term immunity to SARS-CoV-2 involves complex and multifactorial mechanisms, including the action of long-lived plasma cells and coordination between the humoral and cellular immune responses^{7,10}. It is not known what proportion of exposed individuals will exhibit a memory antibody response, although early data suggest that ~10% of individuals recover from SARS-CoV-2 infection yet have no detectable antibodies^{25,26}.

In addition to the humoral response, cellular responses play a central role in SARS-CoV-2 immunity^{10,27}. Indeed, the majority of patients diagnosed with COVID-19, including convalescent patients across a wide spectrum of disease severity, generate CD8+ and CD4+ T-cell responses^{19,28}, which have been associated with milder disease and protection from infection^{29,30}. T cells also play a critical role in activating the humoral response and can precede antibodies to serve as the first sign of the immune response to SARS-CoV-2 infection, particularly in asymptomatic or mild illness^{20,31}. SARS-CoV-2-specific T cells are persistent, remaining elevated at least 6 months post-infection, in some cases in the absence of

seroconversion^{2,32-34}. Finally, aberrant T- or B-cell responses have been implicated in the immune dysregulation underlying severe COVID and inflammatory sequelae including multisystem inflammatory syndrome in children (MIS-C) and in adults (MIS-A)^{35,36}, myocardial involvement^{37,38}, and post-acute syndromes such as “long COVID³⁹.” Exploration of the precise contributions and timing of both humoral and cellular responses is needed to fully understand the biological basis for long-term immunity to SARS-CoV-2 infection and its associated complications. This has become particularly salient with the advent of mass vaccination strategies for COVID-19, where identifying the correlates of vaccine-mediated immunity is central to assessing the durability of protection, whether pre-existing immunity influences the vaccine response⁴⁰, and whether recently-reported viral escape mutants with enhanced infectivity⁴¹ can evade vaccine-induced immunity.

A number of features inherent to the biology of the T-cell immune response make it a desirable target for identifying and tracking disease exposure. The cellular immune response is: 1) sensitive to very small amounts of antigen; 2) specific, binding only to specific antigens; 3) naturally amplified through clonal expansion; 4) systemic, as T-cell clones circulate in the blood; and 5) persistent, as it is maintained in long-term memory. Here we describe the implementation and extensive clinical validation of T-Detect™ COVID, a novel high-throughput assay to determine recent or prior SARS-CoV-2 infection based on T-cell receptor gene sequencing and subsequent repertoire profiling from whole blood samples, following US Food and Drug Administration guidance “*Policy for Coronavirus Disease-2019 Tests During the Public Health Emergency (Revised) May2020.*” We demonstrate high positive and negative percent agreement of this assay to identify or exclude prior SARS-CoV-2 infection in PCR-confirmed SARS-CoV-2

cases across several cohorts and longitudinal timepoints. We also show that the assay has equivalent or better performance than commercially-available EUA antibody tests at all timepoints evaluated⁴², and lacks cross-reactivity to several viral and/or respiratory pathogens.

METHODS

Ethics

All samples were collected pursuant to an Institutional Review Board (IRB)-approved clinical study protocol. For residual samples collected under prospective study protocols, informed consent was obtained from participants. All other samples from cohorts described below were collected as clinical remnant samples. (See Supplement for detailed information).

Clinical Cohorts

Clinical specimens were collected via distinct study arms: 1) a retrospective arm with SARS-CoV-2 positive and negative residual samples from prior research studies and remnant clinical samples; and 2) a prospective arm to collect samples from participants with symptoms compatible with COVID-19 and testing either positive or negative by SARS-CoV-2 RT-PCR. These two study arms provided samples to demonstrate the clinical agreement of the T-Detect™ COVID Assay to determine the PPA and NPA. Study populations are described below and in the Supplement.

PPA Study Cohorts

The primary PPA study evaluated residual blood samples (N=222) from subjects diagnosed with SARS-CoV-2 infection based on the EUA Abbott RealTime SARS-CoV-2 RT-PCR test from a single US reference lab (New York) (Table 1).

Secondary PPA assessments were performed using both retrospectively and prospectively collected samples from multiple cohorts (N=77; ImmuneRACE and ImmuneSense™ COVID-19 cohorts, Supplement) and identified as positive based on a variety of EUA testing methods performed by a number of different labs. Given the potential for variability in RT-PCR performance given the use of numerous tests by multiple labs, samples were categorized by days since symptom onset (Table 1).

NPA Study Cohorts

The primary NPA included 124 retrospective frozen clinical remnant blood samples collected prior to December 2019 (Table 2) and thus presumed negative for SARS-CoV-2 infection. These samples were collected over two years, during all months (including cold/flu season), and from diverse geographical areas in the United States (Table 2).

The secondary NPA study included blood samples from subjects enrolled prospectively (ImmuneSense COVID-19) from Oct-Nov 2020 who presented with SARS-CoV-2 symptoms but tested negative for SARS-CoV-2 using RT-PCR EUA, BioFire RP V2.1, and EUA antibody tests (Table 2).

Clinical Specimens

From all sources, whole blood samples were collected in EDTA tubes, frozen, and shipped to Adaptive for immunosequencing. Paired serum samples were tested using two different EUA antibody assays: 1) Elecsys® Anti-SARS-CoV-2; Roche (all isotypes); and 2) SARS-CoV-2 Antibody, IgG; LabCorp. Detailed serology assay information is in the Supplement.

Classifier Development and Training

We have previously described the development of a SARS-CoV-2 classifier based on TCR β DNA sequences from blood samples². Briefly, one-tailed Fisher's exact tests were performed on all unique TCR sequences comparing their presence in SARS-CoV-2 PCR-positive samples (n=784) with negative controls (n=2,447) to generate a list of SARS-CoV-2-associated sequences which are exclusive to, or greatly enriched, in PCR-positive samples. These sequences were used to create a classifier by logistic regression with two dependent variables, the number of unique TCR β DNA sequences encoding a SARS-CoV-2-associated sequence and the total number of unique TCR β DNA sequences in the sample. The diagnostic model threshold is set to demonstrate 99.8% specificity against a set of 1,657 held out negative controls not used in training².

T-Detect COVID Assay

Process Overview

The T-Detect COVID Assay consists of 1) a core assay designed to sequence and quantify rearranged TCR β sequences from gDNA extracted from peripheral blood and 2) diagnostic software, which applies a COVID-specific algorithm to the TCR β sequence repertoire data to determine a result. The system consists of reagents, instrumentation, software and instructions needed to perform the process steps as summarized in Figure 1.

Sample Collection and Processing

Peripheral whole blood is collected in a 10mL EDTA vacutainer tube and shipped overnight at ambient temperature to the Adaptive clinical laboratory. Upon receipt it is accessioned and

stored refrigerated at 4C until processed that same day via automated gDNA extraction or stored frozen at -80C if extraction is at a later date.

Sample and Library Preparation, Sequencing, and Pipeline Analysis

Detailed methods for sample preparation, immunosequencing, and pipeline analysis have been described previously^{1,2}. Briefly, a target gDNA sample input of 18µgs is isolated from 2mL of fresh or frozen peripheral whole blood (6mL is requested). This target gDNA input ensures that samples achieve a minimum unique productive rearrangements (UPR) input QC specification. A multiplex PCR strategy with synthetic TCRβ molecules added to each reaction is used to amplify rearranged TCRβ sequences from gDNA. PCR libraries are loaded together on a single sequencing run and sequencing performed using the Illumina NextSeq 500/550 System. Sequence data are extracted and reads are attributed to data derived from biological vs. synthetic templates to derive template estimates for each identified receptor sequence as well as input cell counts.

T-Detect COVID algorithm

The COVID-specific algorithm (classifier) which was developed as described above and locked prior to initiating any of the T-Detect COVID validation studies is applied to the core assay output. The classifier identifies and quantifies any SARS-CoV-2-associated TCRs from a predetermined list of several thousand SARS-CoV-2-associated TCRs and also quantifies non-SARS-CoV-2 TCR sequences. These factors are mathematically combined into a score representing the relative enrichment for SARS-CoV-2-associated TCR sequences. This score is

compared to a pre-specified threshold derived during algorithm training to classify the patient sample as positive or negative for an immune response to SARS-CoV-2.

RESULTS

Public enhanced sequences associated with SARS-CoV-2 infection distinguish cases from controls.

Initial development of the COVID classifier utilized public enhanced SARS-CoV-2 sequences from two cohorts, Discovery Life Science (DLS, from New York, USA) and NIH/NIAID (from Italy), comprising a total of 483 cases, with 1,798 controls collected before the emergence of SARS-CoV-2 in 2020. A total of 1,828 enhanced SARS-CoV-2 sequences were identified from this first dataset which collectively distinguish cases from controls (Figure 2a). Notably, these enhanced sequences were also substantially enriched in 397 cases from three additional held-out cohorts: ISB (Institute of Systems Biology's Covid-19 Immune Response Study; Seattle, WA), H12O = (Hospital 12 de Octubre; Madrid, Spain), and BWNW = (Bloodworks Northwest; Seattle, WA) but not seen at the same elevated rates in 1,702 additional held-out controls (Figure 2b).

As additional data enabled identification of more SARS-CoV-2 associated TCRs to improve performance of the classifier², our final classifier was trained using 784 cases from all five cohorts referenced above (and in Supplemental Table 1), as well as 2,447 controls. We then set the diagnostic model threshold to 99.8% specificity on an independent set of 1,657 negative controls not used in training. The final classifier includes a total of 4,470 SARS-CoV-2 associated sequences. The classifier's performance appears robust to potential confounders such

as age and sex (Figure 3a,b), and its performance has been tested in several independent studies^{2,42}, suggesting equal or better sensitivity to antibody serology testing.

High Positive Percent Agreement (PPA) with SARS-CoV-2 PCR

Two separate positive percent agreement (PPA) studies were undertaken to evaluate T-Detect COVID Assay performance in subjects with confirmed positive SARS-CoV-2 PCR: a primary PPA analysis relative to days since diagnosis and a secondary PPA analysis relative to days from symptom onset. In the primary PPA study, 205/222 samples tested were from unique subjects and passed all QC and threshold requirements making them eligible for analysis. In the secondary PPA study, all 77 samples tested were from unique individuals, passed QC and threshold requirements, and were included for analysis. Samples were tested out to a maximum of 106 days from symptom onset. The PPA for various timepoints is displayed in Table 3. PPA for the T-Detect COVID Assay was highest (97.1%) in the timeframe of ≥ 15 days since diagnosis as well as ≥ 15 days since symptom onset (94.5%). (Table 3).

High Negative Percent Agreement (NPA) in presumed and/or confirmed SARS-CoV-2 negative samples

Two separate negative percent agreement (NPA) studies were undertaken to evaluate T-Detect COVID Assay performance: a primary NPA analysis of retrospectively sourced whole blood samples from pre-pandemic timepoints (July 2017- Nov 2019) and thus presumed SARS-CoV-2 negative, and a secondary NPA analysis of prospectively collected samples from symptomatic but SARS-CoV-2 test negative subjects. In the primary NPA study, 87 of 124 samples were from unique individuals, passed all standard QC and assay threshold requirements, and were used for

analysis, yielding an NPA of 100% (Table 4). The majority of failure samples were due to failure to meet assay QC metrics or assay specific thresholds. Due to the retrospective sourcing of these samples, the collection conditions and biological/disease context of these samples was variable.

The secondary NPA study assessed T-Detect COVID Assay performance prospectively in subjects presenting with compatible symptoms but testing negative for SARS-CoV-2 using RT-PCR (BioFire RP2.1 EUA) and EUA antibody tests. Of 79 subjects meeting these criteria, no samples failed QC or performance thresholds and all were included for analysis, yielding an NPA of 98.7% (Table 4).

Equivalent or Greater PPA Than EUA Antibody Tests in Confirmed SARS-CoV-2 Cases

Additional analyses compared the PPA of T-Detect COVID Assay relative to results from serology-based antibody testing in paired SARS-CoV-2 positive samples from 77 unique subjects (EUA RT-PCR), and demonstrated PPA as high or higher than serology, particularly in early phases of infection (Table 5).

Lack of cross-reactivity with other viruses/pathogens

The biology of the T-cell mediated response to infection inherently requires specificity between the TCRs in SARS-CoV-2 positive patient samples and the cognate antigens unique to SARS-CoV-2. The classifier development for this assay leveraged this biologic mechanism. The clinical call threshold was established by utilizing 1,657 controls/known negative samples collected in the U.S. prior to December 2019, from populations with a high prevalence of

vaccination against, or infection with, potentially cross-reactive viruses. This approach yielded a clinical call threshold with an expected specificity of 99.8%.

Specificity was verified in a set of blood and PBMC samples collected from individuals infected with Influenza A/B, *Haemophilus influenzae b*, HIV, HBV and/or HCV to assess potential cross-reactivity. No samples tested positive using the T-Detect COVID Assay (Table 6).

DISCUSSION

The COVID-19 pandemic has accelerated the development of myriad diagnostic testing strategies and platforms. Despite the critical roles of both humoral and cellular immune responses in SARS-CoV-2 infection and recovery, serologic testing is the predominant means of assessing previous infection, population-level prevalence and incidence, and potential immunity. Serology tests offer advantages of relatively low cost, fast turnaround time, and scalability; at the time of this publication, over 100 SARS-CoV-2 serologic tests are available for clinical use including over 60 with EUA status⁴³. However, the limitations of serologic testing, including high variability in test performance across platforms and antibody isotypes tested¹⁸, waning or loss of antibody signal over time^{11,13,14}, and absence of detectable antibodies in up to 10% of individuals including those with immunocompromising conditions^{25,26}, expose unmet clinical and public health needs for immunologic testing strategies for SARS-CoV-2 that are consistent, durable, and more informative.

Using TCR gene sequencing from whole blood samples, we describe a sequence-based assay to identify recent or prior SARS-CoV-2 infection which demonstrates high PPA (>97% beyond 15

days following diagnosis), high NPA in presumed or confirmed negative SARS-CoV-2 infection (~100%), equivalent or higher PPA compared to commercially available EUA serology tests, and lack of cross reactivity with a number of viral and/or respiratory tract pathogens. This performance was consistent across several retrospective and prospective cohorts and longitudinal sampling timeframes. Utilizing this approach in a real-world setting, we have shown previously that robust T-cell signals are persistent at least 6 months after primary SARS-CoV-2 infection⁴², consistent with other reports⁴⁴. In the SARS-CoV-1 pandemic, detectable virus-specific T-cell responses were observed in recovered individuals up to 17 years later²¹. In direct real-world comparisons with serologic testing, we have observed up to a 20% lower sensitivity of commercially available antibody tests in identifying prior SARS-CoV-2 infection compared to T-Detect COVID, with greater reductions in serology performance occurring at later timepoints following infection⁴². Finally, we have reported a direct correlation between the magnitude of the measured SARS-CoV-2 T-cell response (in depth and breadth) and prior disease severity^{11,42}.

These observations support the potential clinical utility of T-cell profiling in the COVID-19 pandemic as a means of risk stratification of disease progression and outcomes, detection of remote prior infection, informing public health and surveillance strategies, and clarifying the correlates of immune protection by providing a more comprehensive characterization of the immune response. We have previously applied our statistical classification framework based on immunosequencing data and T-cell repertoire profiling in determining CMV serostatus as a proof of principle¹. The generation, validation, and application of different algorithms to immunosequencing data has the potential to yield clinical insights across multiple disease areas, particularly in infectious diseases and autoimmunity.

Robust T-cell profiling can also inform vaccine development. Vaccines targeting SARS-CoV-2 are capable of inducing type 1 helper T-cell (Th1) responses, in addition to high levels of binding and neutralizing antibodies that decline over time^{4,45-47}. Indeed, Th1-skewed responses have been shown to drive protective humoral and T-cell responses in patients receiving vaccines directed against other viruses⁴⁸. Thus, a combination of serological testing and high-throughput T-cell repertoire profiling could be beneficial for fully characterizing the nature of the immune response to SARS-CoV-2 vaccination, including assessment of the T-cell response and potential immune escape in recently-described viral variants that have evidence for increased infectivity and transmission⁴¹.

Finally, understanding the immune response to SARS-CoV-2 is critical for elucidating the etiology of immune dysregulation in severe COVID-19 and inflammatory sequelae. Recent data suggest that patients with severe COVID-19 may develop autoantibodies that target proteins involved in the humoral or cellular response, resulting in decreased levels of B cells or T cells⁴⁹. Similarities to Kawasaki's disease have led some to propose that multisystem inflammatory syndrome in children (MIS-C) and in adults (MIS-A), rare complications of SARS-CoV-2 infection, may result from aberrant T- or B-cell responses to the virus^{35,36}. A subset of patients with COVID-19 also present with cardiomyopathy, viral myocarditis or one of a spectrum of syndromic features associated with "long COVID," all of which have been linked to immune dysfunction³⁹. Comprehensive, high-throughput methods of interrogating the cellular immune response in these conditions can provide important clinical insights.

We acknowledge several study limitations, including small samples sizes in some cohorts tested (<15 days post-symptom onset), very limited data from pediatric cohorts (<18yo), and the lack of availability of other seasonal human coronavirus (HCoV) samples for cross-reactivity testing. For the latter, we made extensive efforts to locate retrospective samples for subjects with common respiratory infections but were unsuccessful as blood is not commonly drawn in the clinical diagnosis or treatment of these respiratory viruses. Importantly, there is a high reported prevalence of antibodies against each of the four HCoVs, with greater than 98% of individuals displaying antibodies against 3 of the 4 common strains⁵⁰. Therefore, a significant number of our controls would be expected to have immune responses against HCoVs, adding confidence to the specificity of our TCR signal.

Diagnostic, therapeutic, and vaccine development for COVID-19 have proceeded at unprecedented speed and scale. T-Detect COVID is the first TCR sequencing-based assay for interrogation of the cellular immune response in SARS-CoV-2, which demonstrates $\geq 95\%$ positive agreement in identifying prior exposure/infection with $\sim 100\%$ negative agreement and equivalent or higher performance than commercial EUA serologic testing. As such, it can provide critical insights into disease pathogenesis, severity, recovery, and protection. Future studies will help establish the merits of this approach for immunology research, vaccine/drug development, and public health/surveillance strategies.

Table 1. Description of RT-PCR positive SARS-CoV-2 samples used for primary & secondary analyses

	Primary Analyses	Secondary Analyses	
Cohort name	Discovery Life Sciences (DLS)*	ImmuneRACE*	ImmuneSense COVID-19*
Cohort information	Clinical remnant samples from subjects that were positive for SARS-CoV-2	Retrospective use of residual samples from a prior research study with confirmed SARS-CoV-2 infection via medical record search (NCT04494893)	Prospective collection of individuals being tested for SARS-CoV-2, included participants that tested positive for SARS-CoV-2 (NCT04583982)
Number of unique samples	N = 222	N = 69	N = 8
Study population	Basic demographics, from a New York reference lab	Enrolled ages 18-89, samples collected nationwide, 24 virtual locations throughout the US	Enrolled ages 18-89, two clinical drive-thru testing sites in New Jersey
Sample types PCR Comparator test	Frozen whole blood Abbott RT-PCR SARS-CoV-2 EUA	Frozen whole blood Multiple independent EUA authorized test methods	Frozen whole blood Abbott RT-PCR SARS-CoV-2 EUA

*A detailed description of these cohorts is provided in the Supplement

Table 2. Description of SARS-CoV-2 negative samples for primary and secondary NPA

	Primary NPA	Secondary NPA
Cohort Name	Discovery Life Sciences (DLS)*	ImmuneSense COVID-19*
Cohort Details	Retrospective collection	Prospective collection
Number of Unique Negative Samples	N=124	N=79
Study population	Diverse populations collected within the US upon presentation to clinic with a variety of symptoms, including respiratory illnesses	Single site collection, New Jersey
Dates of collection	Jul. 2017 – Nov. 2019	Oct. - Dec. 2020
Sample types	Frozen blood	Frozen blood
Nasopharyngeal Test		Abbott RT-PCR SARS-CoV-2 EUA
Comparators test at time of collection		BioFire RP 2.1 EUA
Antibody Test Comparators at time of collection		Abbott Architect SARS-CoV-2 IgG Roche Elecsys Anti-SARS-CoV-2

*A detailed description of these cohorts is provided in the Supplement

Table 3. Positive Percent Agreement (PPA) of T-Detect COVID Assay with SARS-CoV-2 RT-PCR according to days since symptom onset or days since diagnosis.

Days Since Diagnosis	RT-PCR+ Samples (N)	T-Detect Positive (N)	T-Detect PPA (95% CI)
0-7 days	35	25	71.4 (53.7 - 85.4)
8-14 days	33	31	93.9 (92.7 - 99.3)
≥15 days	137	133	97.1 (92.7 - 99.2)
All (range 0-91 days)	205	N/A	N/A

Days Since Symptom Onset	RT-PCR+ Samples (N)	T-Detect Positive (N)	T-Detect PPA (95% CI)
0-7 days	13	7	53.8 (25.1 - 80.8)
8-14 days	9	7	77.8 (40.0 - 97.2)
≥15 days	55	52	94.5 (84.9 - 98.9)
All (range 0-106 days)	77	N/A	N/A

Table 4. Negative Percent Agreement (NPA) of T-Detect COVID Assay with pre-pandemic samples sourced retrospectively (DLS) and prospectively enrolled subjects (ImmuneSense COVID-19) negative for SARS-CoV-2 by EUA RT-PCR and antibody testing.

Cohort	Samples (N)	T-Detect Negative Results (N)	NPA (95% CI)
DLS	87	87	100 (95.8 – 100)
ImmuneSense COVID-19	79	78	98.7 (93.1 – 99.97)

Table 5. PPA of T-Detect COVID Assay results compared to serology-based assays in paired samples.

Days Post Diagnosis	N Samples	T-Detect COVID PPA (95% CI)	Abbott Architect SARS-CoV-2 IgG PPA (95% CI)	Roche Elecsys Anti-SARS-CoV-2 PPA (95% CI)
0-7	13	53.8 (25.1 - 80.8)	15.4 (1.9 – 45.4)	15.4 (1.9 – 45.4)
8-14	9	77.8 (40 – 97.2)	22.2 (2.8 – 60)	22.2 (2.8 – 60)
≥15	55	94.5 (84.9 – 98.9)	88 (75.7 – 95.5)	90.4 (79 – 96.8)

Table 6. T-Detect COVID Assay results indicating 100% specificity (lack of cross reactivity) in individuals infected with Influenza A/B, *H. influenza b*, HIV, HCV and/or HBV.

Infectious Agent	N Samples	Source/Type	T-Detect Assay Positives
Influenza A	11	Whole Blood	0
Influenza B	11	Whole Blood	0
<i>Haemophilus influenzae b</i>	3	Whole Blood	0
HIV	5	Frozen PBMCs	0
HCV	7	Frozen PBMCs	0
HBV	1	Frozen PBMCs	0

Figure 1. T-Detect COVID Assay process overview

Figure 2. Public enhanced sequences associated with SARS-CoV-2 infection distinguish cases from controls.

Panels (a) and (b) show the number of TCR β DNA sequences in a subject that encode a SARS-CoV-2 enhanced sequence versus the total number of unique TCR β DNA sequences sampled from that subject for a large number of cases and controls. Panel (a) represents the training set to identify this initial list of enhanced sequences (DLS and NIH/NIAID cohorts), and panel (b) represents a hold-out set with no overlap with the training set (ISB, H12O and BWNW cohorts). Both panels show a similar number and separation of enhanced sequences in cases versus controls.

Figure 3. Performance of T-cell classifier to separate SARS-CoV-2 cases from controls is consistent across age and gender.

Performance of T-cell classifier to separate SARS-CoV-2 cases from controls is consistent across ages (a) and in both males and females (b). Both plots report model scores as the untransformed log-odds estimated from the logistic regression classifier. The violin plot in panel (b) visualizes the density of log-odds scores among male and female cases and controls, with median and interquartile range values indicated.

Figure 2. Public enhanced sequences associated with SARS-CoV-2 infection distinguish cases from controls.

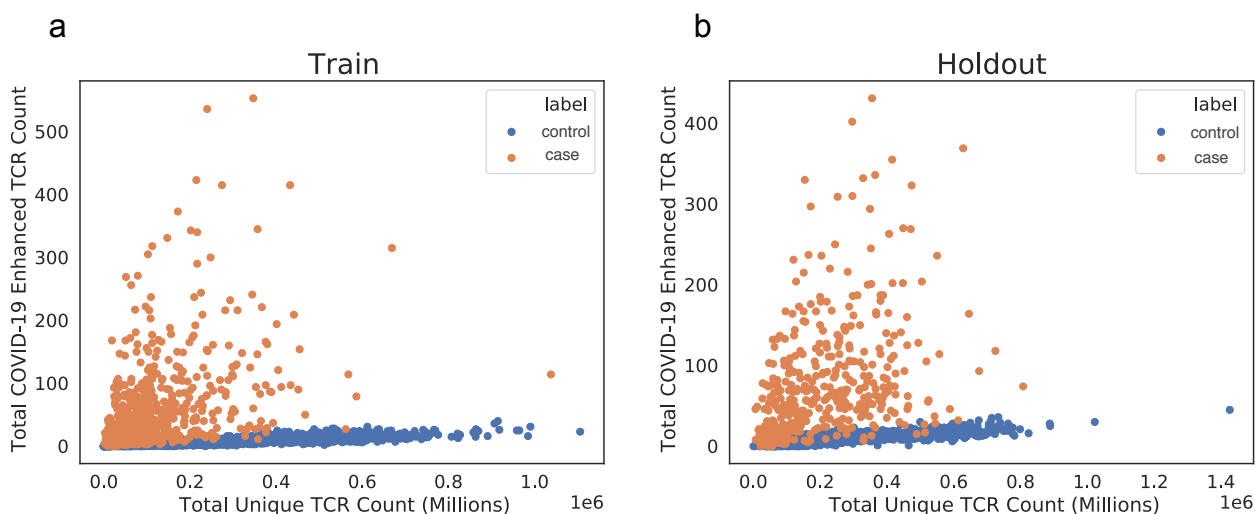

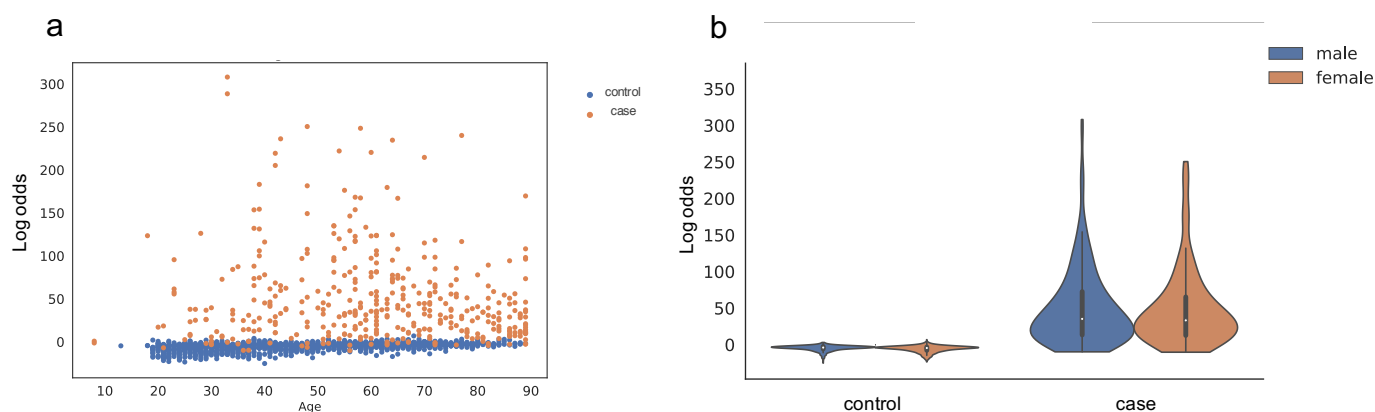

Figure 3. Performance of T-cell classifier to separate SARS-CoV-2 cases from controls is consistent across age and gender.

Supplementary Material

Detailed Study Protocol Information

All samples were collected pursuant to an Institutional Review Board (IRB)-approved clinical study protocol, “ImmuneSense™ COVID-19 Study” (PRO-00781/ADAP-007/WIRB#20202820/NCT04583982.) Residual samples collected under prospective study protocols obtained informed consent from participants under a separate protocol: “ImmuneRACE” (ADAP-006/WIRB# 20200625/NCT04494893). All other samples from cohorts described were collected as clinical remnant samples.

Detailed Methods

Description of cohorts used for secondary analyses

The ImmuneRACE study is a prospective, multi-cohort, exploratory study of participants exposed to, infected with, or recovering from COVID-19 (NCT04494893). Participants from across the United States were consented and enrolled via a virtual study design, with cohorting based on participant-reported clinical history following the completion of both a screening survey and study questionnaire. Whole blood, serum, and a nasopharyngeal or oropharyngeal swab were collected from participants by trained mobile phlebotomists. Participants with a confirmed SARS-CoV-2 test were included as residual, retrospective samples in the CV study.

The ImmuneSense™ COVID-19 Study’s prospective study arm enrolled individuals with symptoms suggestive of COVID-19 who were being tested for SARS-CoV-2 at two drive-thru testing sites in New Jersey. Whole blood, serum, and a nasopharyngeal swab were collected from

participants at study sites. An electronic questionnaire was administered by study staff.

Individuals testing positive via Abbot's RT PCR were included in the secondary PPA analysis.

Individuals testing negative for SARS-CoV-2 using RT-PCR EUA, BioFire RP V2.1, and EUA antibody tests were included in the NPA analysis.

Clinical Specimens

From all sources, whole blood samples were collected in EDTA tubes, frozen, and shipped to Adaptive for immunosequencing. When paired serum samples were collected, they were tested using two different EUA antibody assays: 1) Elecsys® AntiSARS-CoV-2; Roche: qualitative detection of high affinity antibodies to SARS-CoV-2 including all isotypes, but preferentially detects IgG antibodies (<https://www.labcorp.com/tests/164068/sars-cov-2-antibodies>); and 2) SARS-CoV-2 Antibody, IgG; LabCorp: qualitative detection of IgG antibodies to SARSCoV-2 (<https://www.labcorp.com/tests/164055/sars-cov-2-antibody-igg>).

Supporting Table 1: Summary of COVID cohorts used for training of the T-Detect™ COVID classifier:

Study	# Subjects	Median Age	% Female	Study description
DLS	337	70	50.7	Whole blood samples collected during routine care in acute and convalescent phases, procured through Discovery Life Sciences (Huntsville, AL)
NIH/NIAID	146	68	30.8	Whole blood samples collected in Brescia and Monza, Italy during active infection, and provided to the NIAID (Bethesda, MD) for DNA extraction
ISB	83	63	55.4	Whole blood samples collected under the INCOVE project at Providence St. Joseph Health (Seattle, WA); subjects were enrolled during the active phase and monitored through disease

H12O	156	64	37.2	Whole blood samples were collected at the Hospital Universitario 12 de Octubre (Madrid, Spain) during the active or convalescent phase
BWNW	62	54	48.4	Whole blood samples from convalescent subjects collected at Bloodworks Northwest (Seattle, WA)
