Abstract

Purpose: Little is known on the mortality rate in COVID-19 related acute metabolic emergencies, namely diabetic ketoacidosis (DKA), hyperglycaemic hyperosmolar state (HHS), combined DKA/HHS, and euglycaemic diabetic ketoacidosis (EDKA).

Methods: A systematic literature review was conducted using EMBASE, PubMed/Medline, and Google Scholar from January 1, 2020 to January 9, 2021 to identify all case report series, cross-sectional studies, and meta-analyses of case reports describing mortality rate in DKA, HHS, and EDKA, in COVID-19 patients. The Joanna Briggs Institute critical appraisal checklist for case reports was used for quality assessment.

Results: From 313 identified publications, 4 fulfilled the inclusion criteria and analyzed qualitatively and quantitatively. A systematic review and meta-analysis with subgroup analyses examined mortality rate in a total of 152 COVID-19 patients who had developed DKA, HHS, combined DKA/HHS, or EDKA. Combined mortality rate and confidence intervals (CI) were estimated using random effects model. The study was registered to PROSPERO database (ID: 230737).

Results: Combined mortality rate was found to be 27.1% [95% CI: 11.2-46.9%]. Heterogeneity was considerable (I²=83%; 95% CI: 56-93%), corrected to 67% according to Von Hippel adjustment for small meta-analyses. Funnel plot presented no apparent asymmetry; Egger’s and Begg’s test yielded in P=0.44 and P=0.50, respectively. Sensitivity analysis failed to explain heterogeneity.

Conclusion: COVID-19 related acute metabolic emergencies (DKA, HHS, and EDKA) are characterized by considerable mortality; thus, clinicians should be aware of timely detection and immediate treatment commencing.

Key words:
COVID-19, diabetic ketoacidosis, hyperglycaemic hyperosmolar state, euglycaemic diabetic ketoacidosis, meta-analysis
Text

Introduction:

Diabetes mellitus (DM) has been recognized as a major risk factor for unfavorable outcomes in patients with COVID-19 caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) [1]. The underlying pathophysiology of COVID-19 and DM intertwining has not been totally explained; however, diabetes patients have an increased risk of infection and acute respiratory distress syndrome compared with the general population [2] [3] [4] [5] [6], while direct cytopathic effects of SARS-CoV-2 on pancreatic b-cell populations have been proposed [7].

COVID-19 is associated with hyperglycaemic emergencies as diabetic ketoacidosis (DKA), hyperglycaemic hyperosmolar State (HHS), euglycaemic diabetic ketoacidosis (EDKA), and combined DKA/HHS [8] [9]. The over-activity of immune system might further explain COVID-19-related severe and resistant to conventional therapy DKA episodes [10]. High mortality in COVID-19 and diabetic ketoacidosis has been reported in a single letter [11]. In contrast, two small case series exhibited significantly lower mortality rates that range from 7.7% [8] to 12.9% [12]. Additionally, a few dozen of case reports concerning acute emergencies related to glucose metabolism in COVID-19 patients have been reported, all reviewed in a very recent meta-analysis [13].

The present study aimed to provide further evidence regarding the mortality rate in COVID-19-related acute metabolic emergencies (DKA, HHS, combined DKA/HHS, and EDKA) by identifying all relevant studies and summarize their results.
Materials and Methods:

Literature search

A systematic literature review was conducted using PubMed/MEDLINE and EMBASE databases from January 01, 2020 until January 09, 2021 to identify all case report series, cross-sectional studies and meta-analyses of case reports written in English and describing mortality rate in DKA, HHS, combined DKA/HHS, and EDKA in COVID-19 patients. The Google Scholar and ResearchGate databases were used as an additional pool of published data, dissertations and other unpublished work; an iterative search was performed until no additional publication could be traced. Personal communication was followed where needed. The relevant protocol was registered in PROSPERO database on January 10, 2021 (ID: 230737).

Study selection

Eligible studies were all that (1) are written in English; (2) are either report series or cross-sectional-studies or meta-analyses of case reports; (3) report mortality rate in COVID-19 patients who had developed either DKA, or HHS, or EDKA, or combined DKA/HHS or enough data to compute it; (4) report a relevant measure of statistical significance; (5) are not duplicates.

Six reviewers (V.P., M.-V.K., N.T., S.-A.B., P.A., D.-G.-Z.) screened the total number of initially identified studies, applied eligibility criteria and selected studies for inclusion in the systematic review working simultaneously as three independent couples of investigators (one for screening and the other for checking decisions). These three couples were blinded to each other's decisions. D.F. was responsible to dissolve any disagreement. No specific software was used for recording decisions; all data were transformed to a suitable Word table. Sources of financial support were traced where possible.

Outcome measures

The present study was conducted in accordance to the MOOSE reporting guidelines for observational studies [14]. Mortality rates were compared between different types of acute metabolic emergencies in diabetes (DKA, HHS, EDKA, and DKA/HHS) was performed. AMSTAR 2 checklist was used to confirm the high quality of the present meta-analysis [15].

Data extraction

A structured data collection was used to extract the following data from each eligible study: title of the study, name of the first author, year of publication, study design, country where the study was conducted, total number of patients per type of acute metabolic emergency, total number of survivors, and total number of non-survivors. The data extraction process was carried out by six reviewers (V.P., M.-V.K., N.T., S.-A.B., P.A., D.-G.-Z.) who performed data extraction working simultaneously as three independent couples of investigators (consisting of one for extracting data and another for checking the extracted data); the process performed manually and the
three couples were blinded to each other’s decisions. D.F. closely observed the process and was responsible for any discordance.

**Quality assessment of the studies**

The Joanna Briggs Institute (JBI) critical appraisal checklist for case reports, which includes 8 questions addressing the internal validity and risk of bias of case reports designs, particularly confounding and information bias, in addition to the importance of clear reporting, was used for quality assessment of case series [16] [17]. All studies that failed to fulfill requirements of first six questions were considered as of “suboptimal quality”; controversially, an “optimal quality” remark was given. Moreover, the JBI critical appraisal list for case control studies, which includes 12 questions addressing the internal validity and risk of bias of case control studies, was used for quality assessment of case series [16] [17]. All studies that were characterized as of “fair” or “poor” quality were considered as of “suboptimal quality”; controversially, an “optimal quality” remark was given. Furthermore, quality of evidence was approached using GRADE (Grading of Recommendations, Assessment, Development and Evaluations), transparent framework for developing and presenting summaries of evidence [18-20]. GRADE level of evidence was rated down for risk of bias, imprecision, inconsistency, indirectness, and publication bias, whereas was rated up for large magnitude of effect.

The process was carried out by six reviewers (V.P., M.-V.K., N.T., S.-A.B., P.A., D.-G.-Z.) who performed quality assessment as three independent couples of investigators; the process performed manually and the three couples were blinded to each other’s decisions. In case of disagreement within a couple, D.F, who closely observed the process, was responsible to dissolve any discordance.

**Data synthesis**

Data synthesis was performed using MedCalc® Statistical Software version 19.6 (MedCalc Software Ltd, Ostend, Belgium; https://www.medcalc.org; 2020). As effect estimates, mortality rates were extracted from each study and combined together using the random effects, generic inverse variance method of DerSimonian and Laird, which assigned the weight of each study in the pooled analysis inversely to its variance [21]. Random-effects model allows generalizing common effect size beyond the (narrowly defined) population included in the analysis [22]. However, as $I^2$ has a substantial bias when the number of studies is small (positive when the true fraction of heterogeneity is small and negative when the true fraction of heterogeneity is large), the point estimate $I^2$ should be interpreted cautiously when a meta-analysis has few studies; in fact, in small meta-analyses, confidence intervals should supplement or replace the biased point estimate $I^2$ [23].

**Statistical analysis**

Analysis of publication bias (small size effect) was performed by funnel plot visualization for asymmetry and use of Egger’s and Begg’s tests. Heterogeneity was based on Q test and $I^2$; Q test P value <0.10 and/or $I^2$ >50% was indicative of significant heterogeneity and was further analyzed. Analysis of heterogeneity was performed through sensitivity analysis focusing on types of studies, types of acute metabolic emergencies, quality assessment, and GRADE level of evidence to seek whether qualitative or quantitative interaction exists. Univariate comparisons were performed with the use of Pearson’s Chi-square test for discrete variables. All
statistical tests were carried out using IBM SPSS Statistics software, version 26.0.0.0, for Windows (IBM Corp ©).
Results:

Study characteristics
During the final pre-run search prior to the final analysis carried out on January 7, 2021, 313 potentially relevant publications were identified through a thorough search of literature; 174 in EMBASE, 138 in PubMed/Medline, while two more publications of interest were identified through Google Scholar. A single source of unpublished data of interest was detected. No personal contact with any author that considered necessary contributed any additional information.

After the exclusion of 141 duplicates, all the remaining 173 publications were initially reviewed based only on title and abstract; 110 excluded as being ineligible. Thus, 63 full-text publications were further assessed for eligibility; from these, 39 failed to fulfill the eligibility criteria. The remaining 4 publications included in qualitative synthesis and quantitative synthesis/statistical analysis. These publications included 152 patients (Figure 1).

All characteristics regarding title of the study, name of the first author, country where the study was conducted, type of diabetes-related acute metabolic emergency, total number of survivors, total number of non-survivors, and mortality rate were analytically presented in Table 1.

Quality assessment and Risk of bias
Quality remarks are provided in Table 1; all details concerning quality assessment items as well as GRADE level of evidence are depicted analytically in Table 2 and Table 3, respectively.

Primary outcome
Combined mortality rate was found to be 27.1% [95% CI: 11.2-46.9%] (Figure 2). Heterogeneity was considerable ($I^2=83\%$; 95% CI: 56-93%), corrected to 67% according to Von Hippel adjustment for small meta-analyses; this value was based on an approximation for $I^2=80\%$ yielding a real value 64%, and consequently, an bias leading to 16% overestimation (Supplementary Figure 1).

Publication bias (small size effect)
No significant publication bias (small size effect) was detected as funnel plot presented no apparent asymmetry. Moreover, both Egger’s and Begg’s tests yielded an insignificant result (P=0.44 and P=0.50, respectively).

Analysis of heterogeneity
Sensitivity analysis was carried out according to: i) study type (meta-analyses included vs excluded), ii) emergency type (DKA patients included vs excluded, EDKA patients included vs excluded, HHS patients included vs excluded, DKA/HHS patients included vs excluded), iii) quality assessment (studies of “suboptimal” quality included vs excluded), iv) GRADE level of evidence (studies of “very low” level of evidence excluded vs included); furthermore, sensitivity analysis was performed at single study level. There was no difference as deduced by the inspection of the relevant confidence intervals and thus, sensitivity analysis failed to explain the observed heterogeneity.
Discussion:

In the present study we have demonstrated that diabetes-associated acute metabolic emergencies in COVID-19 patients (DKA, HHS, EDKA, and DKA/HHS) are characterized by considerable mortality, which has been estimated to be 27.1% [95% CI: 11.2-46.9%]. Our findings are in keeping with a recent meta-analysis of 41 case reports carried out by our team, which yielded a mortality rate of 32.4% among 68 patients with known outcome [13]. We are totally aware that including a self-report in a meta-analysis can import a severe bias. However, there are at least four reasons which alleviate this danger: first, the meta-analysis of Papadopoulos et al. exhibits the least deviation from the vertical line of the funnel plot, representing the mean; second, sensitivity analysis did not reveal any profound difference regarding combined mortality rate and I²; third, it is of “optimal” quality and has a GRADE “low” level of evidence, namely the best that a study of such a kind can achieve at first; fourth, it is the most representative as it is the only that includes patients presenting all four different kind of emergencies (DKA, HHS, EDKA, and combined DKA/HHS) as well as patients from 41 different sources.

Armeni et al. had a substantial contribution to the topic by analytically describing 35 patients with COVID-19, 26 of which had either DKA (n=11), or HHS (n=2), or mixed DKA/HHS (n=13). This study, although being a case series, is multicenter and of well established quality [8].

Interestingly, Chamorro-Pareja et al. reported an unusually high mortality rate among 50 COVID-19 patients who presented DKA (50%) [11]. In fact, comparing relevant data from all included studies over a 2x4 contingency table (df=3), a statistically significant result is obtained (Chi-square P=0.014); this variability is partly explained by the meta-analysis of Papadopoulos et al. who reported that, apart from the presence of mixed DKA/HHS, two other parameters, namely the presence of acute kidney injury as well as the necessity for mechanical ventilation of COVID-19 patients (critical illness or disease status 4 illness) are key determinants of outcome [13].

Alkundi et al. report the very intriguing - if not controversial - finding that COVID-19 patients presented with DKA, when compared with COVID-19 patients who had not developed DKA, were more likely to survive (P=0.046). Their analysis was carried out with the use of Kaplan-Meier survival curves. However, the authors did not adjust their finding for potent confounders, using Cox-regression, most probably due to the small number of sample size. As a matter of fact, their result needs at least to be considered cautiously and has to be further evaluated in larger studies [12].

The major limitation of the present study might be dual: first, the combination of data from different kind of studies, namely two case report series, one case-control study, and one meta-analysis of 41 case reports; second, the very small number of studies included. However, as the topic is totally novel, any study that respects adherence to protocol followed, investigates causes of heterogeneity, and assesses the impact of risk of bias on the evidence synthesis might be valuable [24].

A serious query could focus on the decision to proceed to the meta-analysis despite the considerable amount of heterogeneity. However, several reasons might support our approach: 1) there was little evidence of publication bias (as funnel plot did not decline from asymmetry), there was no evidence of small size studies effect (as Egger’s and Begg’s tests were not statistically significant), 3) there was no considerable qualitative interaction.
In conclusion, the present meta-analysis illustrated that COVID-19 related acute metabolic emergencies (DKA, HHS, and EDKA) are characterized by considerable mortality; thus, clinicians should be aware of timely detection and immediate treatment commencing. Future, cumulative evidence are welcome to further enlighten this field.
