Abstract

Introduction: Emotional dysregulation constitutes a serious public health problem in need of novel transdiagnostic treatments.

Objective: To this aim, we developed and tested a one-time intervention that integrates behavioral skills training with concurrent repetitive transcranial magnetic stimulation (rTMS).

Methods: Forty-six adults who met criteria for at least one DSM-5 disorder and self-reported low use of cognitive restructuring (CR) were enrolled in a randomized, double-blind, sham-controlled trial that used a between-subjects design. Participants were taught CR and underwent active rTMS applied at 10 Hz over the right (n= 17) or left (n= 14) dorsolateral prefrontal cortex (dlPFC) or sham rTMS (n= 15) while practicing reframing and emotional distancing in response to autobiographical stressors.

Results: Those who received active left or active right as opposed to sham rTMS exhibited enhanced regulation (ds = 0.21 - 0.62) as measured by psychophysiological indices during the intervention (higher high-frequency heart rate variability, lower regulation duration). Those who received active rTMS over the left DLPFC also self-reported reduced distress througout the intervention (d = 0.30), higher likelihood to use CR, and lower daily distress during the week following the intervention. The procedures were acceptable and feasible with few side effects.

Conclusions: These findings show that engaging frontal circuits simultaneously with cognitive skills training and rTMS may be clinically feasible, well-tolerated and may show promise for the treatment of transdiagnostic emotional dysregulation. Larger follow up studies are needed to confirm the efficacy of this novel therapeutic approach.

Introduction

Emotional dysregulation, defined as a deficit in the ability to reduce or change negative emotional states[1], occurs across several forms of psychopathology [2,3] and drives the severity and duration of a variety of mental health problems[4,5]. Difficulties in emotion regulation can be treated through psychotherapy[2,6-8] in transdiagnostic individuals[9,10]. Transdiagnostic approaches teach emotion regulation skills such as cognitive restructuring (CR), relaxation, and mindfulness[11-14]. However, psychotherapy is considered to be moderately effective in the treatment of emotion dysregulation[9,15] and is still in need for improvement to maximize gains and reduce treatment burden[16]. Specifically, more work is needed to accelerate the process of learning within therapy sessions, to retain skills after therapy sessions, and to help patients generalize in-session learning to out-of-session contexts[17].

One approach to optimize transdiagnostic interventions is to translate findings from basic neuroscience studies on emotion regulation into the development of new interventions. Emerging neuroscientific findings highlight that across several disorders, hypoactivation in prefrontal regions such as the dorsolateral (dlPFC), ventrolateral (vlPFC), and medial (mPFC) prefrontal cortex, and hyperactivation in limbic/paralimbic brain areas, such as the left anterior insula[18,19], characterize difficulties in changing emotional arousal. Brain stimulation can alter pathological brain circuits resulting in translational potential to mitigate problems with emotion regulation. Repetitive transcranial magnetic stimulation (rTMS)[20], in particular, is one type of noninvasive brain stimulation leads to downstream effects through network connectivity, thereby modulating broad brain circuits that underlie psychopathologies [21]. Given the critical role of the dlPFC in the emotion regulation neural network, applying high frequency rTMS --known to have facilitatory effects-- over the dlPFC could have potential to regulate its hypoactivation, enhance synaptic plasticity[22], and, as a result, improve learning of emotion regulation skills. It has been demonstrated that excitatory stimulation of the left dlPFC facilitates disengagement from angry faces[23], while excitatory stimulation of the right dlPFC enhances cognitively-based emotion regulation in healthy adults[24].

Concurrent neurostimulation can be used as an augmentation tool for behavioral interventions, with effects apparent even after one session. For example, rTMS can remediate hypoactive brain circuits by enhancing spontaneous activity in targeted regions (e.g., remediating working memory performance following sleep deprivation[25]). In addition, when combined with a behavioral prime (e.g., food, drug paraphernalia, cues that trigger obsessions), active neurostimulation reduces problematic behaviors (respectively, binge eating, drug use, compulsive behaviors) above and beyond sham stimulation[26-28] in the short term. Past studies have combined rTMS with 16-20 sessions of psychotherapy, demonstrating feasibility[29], with enhanced effects over psychotherapy alone[30] or over cognitive training alone[31]. Taken together, these studies show promise for neurostimulation as an augmentation tool to alter emotion regulation.

This randomized, double-blind, sham-controlled study, using a parallel design, aimed to establish the feasibility, acceptability and preliminary efficacy of enhancing emotion regulation skills training for transdiagnostic clinical adults with excitatory rTMS over the dlPFC, concurrently during an emotion regulation task. We selected cognitive restructuring (CR) as a targeted emotion regulation skill – that involves thinking differently about a situation to reduce negative affect[32,33] -- because

it is generally effective at downregulating emotions[33,34]; it can be implemented across a broad
range of affective contexts[34]; and it engages the same fronto-limbic neural networks on which
neurostimulation has already been tested[35,36]. To establish proof-of-concept and feasibility, we
limited the intervention to a single session and collected high frequency heart rate variability (HF-
HRV) as an objective physiological measure of emotion regulation[37-42]. Using a potentiation
design[43] we hypothesized that receiving active versus sham rTMS in conjunction with CR would
lead to faster recovery from emotional distress during the intervention session, reduced arousal and
increased use of CR during the week after the intervention, and improved emotional dysregulation,
psychopathology and functioning for up to a month following the intervention.

Materials and Methods

Participants and Procedures

This study (N = 83) and an adjunctive supplement (N = 65) were pre-registered together
(NCT02573246), and they ran concurrently from April 2016 to February 2020. The results from the
supplemental study are not included here. We expected moderate to large effect size differences
between regulation during active and sham conditions in our psychophisiological measurements
based on previous findings[24]. A G*Power 3.1[44] power analysis indicated that a total sample size
of forty-two participants (14/condition) in a repeated measures ANOVA (5-measurements) examining
between factors effects, with high correlation between repeated measurements (r = 0.70)[45] would
be needed to observe the a moderate to large effect size (f= .45) with an observed power of .80 and
an alpha of .05.

Out of 83 participants enrolled, forty-seven (8 men; 39 women, mean$_{age}$: 30.02 ± 10.73)
qualified and were randomized to one of three treatment conditions. The first randomized
participant piloted all procedures, and the remaining 46 were considered intent to treat (ITT).
Participants self-reported below-average use of CR when upset, were transdiagnostic and met
criteria for an average of 2.53 (SD = 1.65) current and 4.20 (SD = 1.94) lifetime DSM-5 diagnoses
(SCID-5)[46]. A third of our sample (31.92%) met criteria for at least one personality disorder (SCID-
5-PD)[47]. The CONSORT flow diagram, Figure 2A and the Supplemental Materials detail study flow
and inclusion/exclusion criteria. The study was approved by the Duke University Health System
(DUHS) Institutional Review Board, and participants were paid for the study visits that they attended.

Intake Session

Qualified participants completed a clinical interview, a battery of self-reports, and a
standardized assessment [48,49] which yielded four autobiographical negative emotional arousal
scripts (see Supplemental Materials). Participants were then randomly assigned to active right dlPFC
(n = 17), active left dlPFC (n = 14), or sham stimulation (n = 15), matching for biological sex and use of
psychotropic medication using a minimization algorithm [50,51] and a 1:1:1 ratio. Sham participants
were further randomized using a 1:1 ratio to receive TMS over either the right (n = 8) or left DLPFC (n
= 7).

Intervention Session

Participants returned for the 3.5-hour intervention session within a month of intake (Fig. 2B).
The session started with one-on-one skills training with a trained psychologist, and was focused on
learning and practicing CR. Skills training used established procedures blending psychotherapeutic
approaches [52,53] with instructions in CR that matched prior neuroimaging studies [54] and
included non-specific factors such as unconditional positive regard, attention from the experimenter,
and openenss for disclosure from the participant[43]. Both distancing and reframing CR tactics were
presented and practiced (see Supplemental Materials).

Before and after the intervention session, participants rated on a scale from 0 to 3 (absent -
severe) the intensity of their headache, neck and scalp pain, and hearing impairment. Throughout
the intervention day participants rated subjective units of distress (SUDS; 0 to 9 scale) and
dissociation [55]. Psychophysiological measurements were collected continuously using the BIOPAC
MP-150 recording system (Goleta, CA). The progression of the combined intervention is detailed in
Fig. 2B.

rTMS Parameters. Active or sham rTMS was performed with a figure-8 coil (A/P Cool-B65)
and a MagPro X100 stimulator with MagOption (MagVenture, Denmark). Stimulation was delivered
over the left or right dlPFC, defined according to the 10-20 system [56](Supplementary Fig.1). A
stereotaxic neuronavigation system was used (Brainsight, Rogue Research), and a template brain
(MNI) was registered to each participant's head using anatomical landmarks, to maintain accurate
coil positioning across the session. Twenty trains of 10-Hz rTMS (4 s, 26 s inter-train interval) were
delivered at 120% of rMT [57-59] four times over the course of the intervention session for a total of
3200 pulses. Sham stimulation was delivered using the opposite, shielded face of the same A/P coil.
Sham electrodes delivering a weak electrical current on the scalp [60], in order to mimic the active
TMS-induced somato-sensory sensations were put near the hairline for all participants and were only
activated for sham participants.

Ambulatory Assessment and Follow-Up Visit

Following the intervention participants received 8 calls/day for 7 days, starting the day after
the intervention, at pseudo-random times. On each call participants were asked if they had used CR
since the previous call (yes/no) and their current level of distress (0 to 9). At the end of the week, the
battery of self-reports from intake was administered again via an online link.

Participants returned to the research office a month later to complete a stressor task with a
4th autobiographical stressor and without rTMS (Fig. 2C), an exit interview, and self-reports.
Afterwards, the blind was broken and the experimenter and the subject debriefed.

Measures

The primary outcomes for the study were HF-HRV during emotion regulation and the time it
took to downregulate autobiographically induced distress. During the intervention and follow-up
sessions, each period (e.g., baseline, habituation, stressor, and regulation) was divided into 120-s
bins, and HF-HRV was extracted from the cleaned ECG signal from each bin following established
guidelines [61]. For each baseline, heart rate (HR) was averaged from the last 240 s of the total 300 s,
excluding any disruptions. Time to return to one's HR baseline during the regulation period

(regulation duration) was defined as the amount of time it took from the beginning of regulation for
the continuously monitored HR to reach a value that was lower or equal to the average pre-stimulus
baseline HR. A baseline value for regulation duration was computed as the time it took during
habituation for the person to return to HR baseline after the rTMS driven increased arousal.

Secondary outcomes included acceptability and feasibility metrics, self-reports related to
psychopathology and emotional dysregulation (ERQ, Difficulties in Emotion Regulation Scale --
DERS[62], Outcome Questionnaire -- OQ-45[63], Work and Social Adjustment Scale -- WSAS[64]),
SUDS and use of CR during the ambulatory week. Participants were asked to give their best guess
whether they received real or sham rTMS (forced-choice question) and to rate their confidence in
their response after the intervention and at the 1-week and 1-month follow-up assessments. An exit
interview [29] was administered at 1-month to examine perceived feasibility and acceptability on a
scale from 0 (not at all) to 9 (extremely). Satisfaction was rated on a 0 (low) to 100 (high) scale.

Statistical Analyses

Mixed-effects hierarchical linear models (MMANOVA) with analytically determined
covariance structures were used to analyze the repeated measures data [65] (see Supplemental
Materials for the SPSS syntax for the models used). Estimated marginal means (EMMs) were
compared using LSD corrections for significant main and interaction effects. Effect sizes for these
models were computed using Feingold's formula [66] and interpreted using Cohen's [67]
specifications. To test immediate effects of the intervention, we conducted three analyses examining
HF-HRV, regulation duration, and SUDS using a Benjamini and Hochberg false discovery rate (FDR)
correction [68]($q = 0.10$). See Supplemental Materials for details. Generalized estimated equations
models (GEE) [69] using ordinal logistic models and an independent covariance structure examined
differences between treatment conditions in side effects.

To test near-term effects of the TMS-CR intervention, a hierarchical linear model (HLM) [70]
was used to examine condition differences in SUDS and a GEE binary logistic model (logit link,
unstructured working correlation with robust estimators) [71,72] examined differences in use of CR
(indicated as yes/no on each call) during the ambulatory week. An FDR correction [68] was employed
for these analyses ($q = 0.10$).

To test the long-term effects of the intervention, six MMANOVA models were conducted:
four examining between-condition differences at the 1-week and 1-month follow-up assessments in
ERQ, DERS, OQ-45, and WSAS; and two examining HF-HRV and SUDS during the follow-up stressor
task. An ANCOVA examined differences in regulation duration at follow up. The significance
threshold for the seven long-term analyses was adjusted using an FDR correction [68]. In cases where
significant differences were not found, equivalence testing was employed using the two one-sided
test procedure[73,74] with symmetric equivalence margins of .5 as suggested by others [75,76].

Results

Missing Data

Out of 46 ITT participants, four could not tolerate the target rTMS dose; nevertheless, all

available data are included in the final outcome analyses (see Table 1 for demographics). Across the
variables examined for those included, only 4.3% of the data was missing (Supplemental Materials).

Normality Assumption

At both intervention and follow up, HF-HRV was transformed using the function lg10*(HF-
HRV*1000000) and regulation duration was transformed with a lg10 function. Intervention SUDS
were also transformed to a normal distribution using a square root function.

Tolerability and Acceptability

Participants found the overall study procedures very acceptable ($M_{Acceptability}$ = 7.26, SD = 1.08)
and feasible ($M_{Feasibility}$ = 6.61, SD = 0.79) with no differences between conditions (*ps* > .05).
Participants were 59.40% (SD = 33.51) likely to recommend this treatment to a friend. Participants
reported low distress induced by neurostimulation while they were engaging in CR (M = 2.19; SD =
1.04) and moderate-to-low interference with concentrating from the TMS noise (M= 4.80, SD = 2.47).
When asked the open-ended question "what was it like being in our study?", all participants reported
that they had a positive experience, found CR very useful, and thought it had a positive impact on
their lives. There were no serious adverse events in the study.

There was no significant difference between treatment conditions in headache (Wald χ^2[2] =
0.11, *p* = .95) and neck pain (Wald χ^2[2] = 2.61, *p* = .27). Five participants in the active left condition
(35.71%), eight in the active right condition (47.05%), and six in the sham condition (40.0%) reported
worsened headache after the intervention. One participant in the active left condition reported mild
hearing problems following our procedures. One participant from the active left and four from the
active right condition reported mild scalp discomfort following the intervention. No one experienced
a seizure, and all side effects resolved by the next study contact.

All participants reported being naïve to rTMS at the beginning of treatment. Three
participants in the active conditions and five in the sham conditions believed they received sham
rTMS when asked to guess their condition assignment (χ^2[2] = 5.68, *p* = .06). Nevertheless, the
majority of participants were not confident in their choice (53.5% indicated it could have been either)
or thought they more likely than not received real stimulation (47.4%). All participants who guessed
sham rated their confidence in their assignment as a 5 (uncertain).There was no significant difference
between conditions in confidence about assigned condition right after the intervention (*F*[2,42] =
1.92, *p* = .16), or at the one week (*F*[2,38] = 1.15, *p* = .33), or one month follow up (*F*[2,41] = 0.15, *p* =
.86). These findings suggest that the procedures are feasible and acceptable and that the blinding
procedures described were successful.

The Effect of the Combined Intervention on Immediate Emotion Regulation

To test whether neurostimulation would enhance emotion regulation at the moment when it is
administered, we conducted three MMANOVA analyses using HF-HRV during regulation, SUDS after
regulation, and regulation duration as dependent variables.

Heart Rate Variability Results. The MMANOVA analysis of HF-HRV, using an unstructured

covariance, showed a significant main effect of treatment condition ($F[2, 32.17] = 4.34$, $p = .02$, $p_{FDR} = .03$), time within each regulation period ($F[4, 39.19] = 6.17$, $p < .005$), session baseline ($F[1, 66.70] = 104.27$), and pre-stimulus baseline $F[1, 81.25] = 59.39$, $p < .001$), as well as a significant treatment condition by time interaction ($F[8, 39.24] = 2.77$, $p < .05$). Active rTMS over the left (EMM$_{lg\_HF-HRV}$ = 1.91, S.E. = .04) and right dlPFC (EMM$_{lg\_HF-HRV}$ = 1.86, $S.E.$ = .04) led to significantly higher HF-HRV (i.e., enhanced emotion regulation) when compared to sham rTMS (EMM$_{lg\_HF-HRV}$ = 1.75, $S.E.$ = .04), $ps < .05$ ($ds = 0.21 - 0.31$). The active rTMS conditions were not significantly different ($p = .34$) and were equivalent (90% CI = [-0.38 - 0.46]). LSD-corrected pairwise comparisons of the interaction effect showed a significant difference between active and sham stimulation for the first 6 minutes of regulation ($ps < .05$), and no difference for the last 4 minutes, suggesting that sham participants "caught up" with active participants in their emotion regulation by the end of the regulation period (See Fig. 3). The effect size of the difference between sham and active TMS was largest (Cohen's $d = .45-.53$) in the first 2 minutes of regulation.

Self-Report Results. The experimental instructions (i.e., try to relax, remember a stressor, use CR) successfully modulated distress across conditions ($F[2, 40.32] = 70.97$, $p < .001$; Fig. 4). Participants in the active left rTMS condition experienced significantly lower distress (EMM$_{SR\_SUDS}$ = 1.19; S.E. = .08) during the intervention when compared to sham (EMM$_{SR\_SUDS}$ = 1.43; S.E. = .08; $d = .30$; $p < .05$) and active right rTMS participants (EMM$_{SR\_SUDS}$ = 1.44; S.E. = .08, $d = .32$; $p < .05$; $F_{treatment\_condition}[2, 34.99] = 3.41$, $p = .04$, $p_{FDR} = .06$). LSD-corrected pairwise comparisons did not find a significant difference between right and sham rTMS. The treatment condition by instruction interaction was not significant ($F[4, 40.62] = 1.88$, $p = .13$; see Fig. 4).

Regulation Duration Results. For the 38 participants who had above pre-stimulus baseline HR at the beginning of the regulation period, it took almost twice as long to return to HR baseline during regulation if receiving sham (M$_{sham}$ = 129.08 s, S.D. = 194.57, N = 11) versus active neurostimulation (M$_{active\_right}$ = 65.31 s, S.D. = 97.92, $n = 15$; M$_{active\_left}$ = 74.20 s, S.D. = 110.64, $n = 12$). A MMANOVA using autoregressive covariance structure ($F_{treatment\_condition}[2, 36.48] = 3.14$, $p = .055$, $p_{FDR} = .10$) found that that regulation duration was significantly longer in the sham condition when compared to the active right condition ($p < .05$; $d = .62$) and near significantly longer when compared to the active left condition ($p = .08$; $d = .48$). The active conditions were not significantly different ($p = .58$) and were equivalent (90% CI = [-0.495 - 0.34]).

In summary, we found preliminary evidence that when compared to CR with sham neurostimulation, rTMS administered in conjunction with CR enhances physiological (HF-HRV; regulation duration) and, after left rTMS, self-reported (SUDS) indices of emotion regulation even after controlling for multiple comparisons. Left and right administration of neurostimulation leads to equivalent biological responses.

The Near-Term Effect of the Combined Intervention on Daily Distress and Use of CR

Participants indicated having used CR since the previous call in 785 instances (44.73% of answered calls) and reported SUDs above 0 in 1245 calls (71.30% of answered calls). Calls happened on average every 107.06 minutes (SD = 45.08), with no difference between conditions in the amount of time that lapsed between placed calls ($p > .05$). Participants who received active left rTMS

stimulation reported significantly more likelihood to use CR (EMM = 0.58, SE = 0.04) when compared
to participants who received sham rTMS (EMM = 0.41, SE = 0.05) or right rTMS (EMM = 0.31, SE =
0.04), Wald $\chi^2_{condition}$ (2) = 21.89, p < .001, p_{FDR} = .05.

We also found a significant main effect of treatment condition on daily distress
($F_{treatment\_condtion}$[2, 257.86] = 3.23, p = .04, p_{FDR} = .1). LSD-controlled pairwise comparisons showed that
participants who received active left rTMS reported significantly less average distress during the
ambulatory week (EMM_{sqrt_suds}= 0.95, SE = 0.12) when compared to participants who received active
right rTMS (EMM $_{sqrt\_suds}$ = 1.18, SE = 0.11). The sham group (EMM_{sqrt_suds}= 1.11, SE = 0.12) did not
differ from the other two groups (ps > .05). There was no significant main effect of time or baseline
(ps> .05).

In summary, active left rTMS led to more frequent use of CR compared to sham and right
rTMS, and reduced daily distress when compared to right rTMS. The results remained significant
after applying the FDR correction.

The Long-Term Effect of the Combined Intervention

One Week and One Month Self-Report Results. Paired sample t-tests indicated that all
participants significantly improved in their use of reappraisal (t[42] = 10.53, d = 1.70, p < .001) after
the intervention. Participants were stable in their use of reappraisal from phone screen to baseline
(i.e., before the intervention occurred), t(45) = 1.47, p > .05. After applying the FDR correction, there
were no significant differences between treatment conditions or condition-by-time interactions for
reappraisal, overall difficulties in emotion regulation, overall psychopathology severity or work and
social functioning impairment (ps > .04; Table 2). The differences between conditions at each of the
follow up time points also failed the equivalence test (90% CI included -0.5 or 0.5).

One Month Follow-Up Behavioral and Physiological Results. Participants were successful
during the follow-up stressor task to increase their subjective distress from baseline ($\Delta_{SUDSstressor\text{-}}$
$_{baseline}$= 2.25, S.E. = .35, p < .001) and then regulate it back to baseline ($\Delta_{SUDS\_stressor\text{-}regulation}$= 2.38, S.E.=
.35, p < .001) using a fourth autobiographical stressor and CR as a regulation technique (F_{time}[2,
81.55] = 26.32, p < .001). There were no significant differences between treatment conditions in the
success of regulation when examined via either HF-HRV or SUDS ($F_{HF\text{-}HRV}$[2, 36] = 1.68; F_{SUDS}[2, 99.71]
= 1.00; ps > .05). A univariate GLM test of regulation duration (M = 38.84s, SD =57.27) showed no
significant difference between treatment conditions (p = .78; N = 29). Nevertheless, conditions were
not equivalent (90% CI included -0.5 or 0.5).

In summary, participants maintained their regulation ability at follow up, but no self-reported
or physiological effect of rTMS augmentation could be seen one month after its administration.

Discussion/Conclusion

This proof-of-concept study preliminarily demonstrated the promise of augmenting emotion
regulation skills training and practice with rTMS in a one-time intervention designed to target a
dysregulated neural circuit. Neurostimulation over either the left or the right dlPFC enhanced
immediate emotion regulation according to behavioral, physiological, and self-reported indices. The

augmented gains could be seen up to one week later for those who received left dlPFC stimulation.
Participants tolerated the procedures well, found the approach acceptable, and reported having a
positive experience. These results are encouraging of continued efforts to combine rTMS with skills
training in brief, transdiagnostic interventions.

All participants learned CR in a 45-minute session following a standardized scripted protocol
and then practiced CR on their own autobiographical stressors. The session included nonspecific
therapeutic factors such as positive regard, attention, and invitation to self-disclose difficulties. This
training by itself proved valuable and led to a significant increase in skills use corresponding to a large
effect size (Cohen's d = 1.70). This result is unlikely to represent a regression to the mean but it could
be attributable to the nonspecific factors present across conditions [43]. Future studies should
examine the unique effects of one-time behavioral interventions on emotional dysregulation and
parse out the need for skills training versus the therapeutic benefit of the participant-experimenter
interaction [77].

The addition of active rTMS to CBT training enhanced emotion regulation as measured by HF-
HRV, regulation duration, and self-reported distress. Active stimulation got participants to calm down
faster. Sham participants achieved the same regulation effect over a longer (almost double) time
frame. Therefore, neurostimulation may play an important role in enhancing the utility of the
emotion regulation skill in the moment. Stimulating over the right or the left led to equivalent
physiological outcomes in the moment. Beyond the intervention session, active left rTMS enhanced
the acquisition of CR and reduced daily distress with noticeable effects up to a week. Given that
existing protocols that combine psychotherapy and neurostimulation are 16 to 20 weeks long
[30,78], our approach provides a promising novel paradigm for future research.

To test the superiority of the combination of rTMS and CR, future studies should examine
whether neurostimulation alone can achieve these effects following autobiographical emotional
induction without teaching and practicing an emotion regulation skill. Parsing out whether rTMS
leads to reduced reactivity instead of regulation would also be an important mechanistic question to
achieve additional clarity on. Furthermore, other contextual variables such as expectations given the
novelty of the treatment, treatment setting, personal characteristics, placebo reactivity, and
treatment history should also be examined for their relative contributions to the treatment
outcomes[79].

This study fills a gap in knowledge about the utility of neuromodulation as an enhancing
technique to behavioral interventions in a transdiagnostic clinical sample. We used the standard
10Hz rTMS to enhance cortical excitability in the dlPFC, in line with the findings discussed in the
introduction that point to transdiagnostic hypoactivity in this region during emotion regulation tasks.
We also employed neuronavigation using the 10-20 system. This approach provides a more precise
localization of the dlPFC when compared to the more traditional 5 cm rule [80]. We opted to divide
the rTMS session into 4 epochs in order to make engagement in autobiographical emotion regulation
feasible. This decision was aligned with prior research highlighting that breaks may enhance
facilitatory after-effects [81]. Furthermore, having participants spend more than 10 minutes in
effortful emotion regulation would be difficult to accomplish and receiving rTMS during emotional
induction would dampen the emotional experience [82], reducing the opportunity for regulation. Our

results demonstrate that these decisions did not alter the potential of neurostimulation to enhance
behavioral training and that therapeutic activities, like skills practice, could take place during rTMS
successfully.

The study had some important limitations including the sample size and lack of matched
control group for the skills training component. The study was powered expecting a moderate to
large effect size and we found small to moderate effect sizes, which may suggest that the results are
underpowered. A more stringent approach to defining low CR would have been to only include
those who score 2 SD below the pooled mean. Targeting for rTMS in this study used exterior head
measurements and, therefore, may have not resulted in excitation of a relevant node of the emotion
regulation neural network. The interval between training sessions was short, which may reduce the
effectiveness of skills training [83]. The combination of rTMS with a spaced training or irregular
training protocol may optimize and enhance learning [83]. Finally, It is important to highlight that
bias may exist in the publication of positive neurostimulation results [84] and that additional
scrutiny may be needed for this experimental approach.

The intervention design could also benefit from hypothesis driven optimization. Several
parameters that can improve the efficacy of rTMS have been identified and should be tested in
future iterations of this intervention: targeting networks versus regions[85-87], targeting using
functional MRI with neuro-navigation[20,88], adjusting the inter-trial interval[88,89], and using E-
field modeling [90]. In addition, maximizing the context dependent nature of rTMS by identifying the
optimal time for emotion induction and for neurostimulation onset could also enhance efficacy. On
the behavioral side, refinement of learning parameters such as the spacing between regulation trials
to optimize synaptic plasticity[83], accounting for nonspecific factors, and ensuring successful skills
acquisition and implementation could further enhance the efficacy of the combined intervention.

In summary, our goal was to begin the development of a time-limited combined intervention
for transdiagnostic emotional dysregulation. We found preliminary evidence that rTMS augments
behavioral skills training in the moment, and that the one-time session of combined rTMS-CR
intervention may lead to changes in synaptic plasticity and have effects that last as long as a week.
Our findings provide a promising first step in the development of novel neuroscience-driven
treatment paradigms that address this hard-to-treat, transdiagnostic clinical population.

Statements

Acknowledgement (optional)

Data in the present paper were also presented as part of several conference talks. The authors would like to thank the participants and to acknowledge Lisalynn Kelley, Zach Rosenthal, PhD, Caitlin Fang, PhD, Kevin Haworth, PhD, Megan Renna, PhD, Paul Geiger, PhD, Simon Davis, PhD, Moria Smoski, PhD, Tim Strauman, PhD, Michael Babyak, PhD our research assistants and DUHS staff for their contributions.

Statement of Ethics

<u>Study approval statement:</u> The study was approved by the Duke University Health System Institutional Review Board (approval number: Pro00066383) and pre-registered on ClinicalTrials.gov (NCT02573246).

<u>Consent to participate statement</u>: Written informed consent was obtained before any study procedures began.

Conflict of Interest Statement

The authors have no conflicts of interest to declare. The content is solely the responsibility of the authors and does not necessarily represent the official views of the National Institutes of Health.

Funding Sources

This research and the completion of the manuscript were supported by a Brain and Behavior Young Investigator Award, a Duke internal award, and KL2 award granted to the first author and by the National Center for Advancing Translational Sciences of the National Institutes of Health under Award Number 5KL2TR001115.

Author Contributions

All authors contributed significantly to the present manuscript. Dr. Neacsiu conceptualized and conducted the study. Drs. LaBar, Appelbaum, and Lisanby provided design input, helped problem solve study related issues throughout the study, and contributed to the manuscript preparation. Dr. Beynel conducted the neurostimulation procedures. Dr. Powers completed our physiological preprocessing pipeline. Dr. Szabo served as the study doctor throughout the study.

Data Availability Statement

All data is available upon request.

Figure Legends

Fig. 1.   CONSORT Flow Diagram. CR = Cognitive restructuring; rTMS = repetitive transcranial magnetic stimulation; ITT = Intent to Treat; dlPFC = dorsolateral prefrontal cortex

Fig. 2.   A. Overall study design (with target days since intake when each session was planned to occur), B. Schematic of the TMS-CR intervention. Physiological data were collected during a 300 s rest period (session baseline), followed by the identification of the resting motor threshold (rMT). A 600 s habituation period followed when participants received active or sham rTMS alone while listening to white noise and being instructed to think of nothing in particular. Next, participants were instructed to sit quietly for a 300 s pre-stimulus baseline, followed by instructions to imagine as vividly as possible a negative experience while hearing a 40-s recording of the autobiographical stressor (120 s total), and by instructions to reduce distress using CR (600 s). The rTMS began right after the CR instruction audio was played and continued throughout the regulation period. Every 180s there were prompts to either distance or reframe thoughts related to the autobiographical stressor. Afterwards, there was a break, followed by a second and third administration of the stressor task using the procedures outlined above, but with different personalized stressors presented in a randomized order. C. Schematic of the 1 month follow up stressor task, TMS = repetitive transcranial magnetic stimulation (either active or sham); CR = cognitive restructuring; rTM = resting motor threshold; SUDS = subjective units of distress; DSS = dissociation; SCID = structured clinical interview; DERS = Difficulties in Emotion Regulation; QQ-45 = Outcome Questionnaire – 45; WSAS = Work and social adjustment scale; ERQ = Emotion regulation questionnaire

Fig. 3. Changes in high frequency heart rate variability (HF-HRV; a marker of effective emotional regulation) summarized across the three regulation periods allotted during the intervention, and separated by condition, and by time segment. The original HF-HRV value was measured in seconds^2, multiplied by 100000 and transformed using a log function to achieve normality. Each time point on the graph represents the estimate marginal mean from the LSD pairwise comparisons from the

MMANOVA main analysis which accounts for covariates. Regulation periods followed autobiographical negative emotional inductions.

Fig. 4. Changes in subjective units of distress (SUDS; a self-report marker of negative emotional arousal) summarized across the three experimental periods, and separated by condition, and by instruction provided. The original SUDS value was transformed using a square root function to achieve normality. Each time point on the graph represents the estimate marginal mean from the LSD pairwise comparisons from the MMANOVA main analysis which accounts for covariates. The graph presents data at the end of the pre-stimulus baseline, after the negative emotional induction using the autobiographical stressor, and at the end of the regulation period.

Total # of diagnoses in lifetime	4.71 (1.73)	3.88 (1.80)	3.80 (2.08)
Current Disorders (%)			
Depressive Disorders	50.0	41.2	26.7
Bipolar Disorder	7.1	5.9	0.00
Anxiety Disorders	85.7	76.5	73.3
Lifetime Disorders (%)			
Depressive Disorders	92.9	70.6	86.7
Anxiety Disorders	92.9	82.4	73.3
Substance Use	7.1	17.6	6.7
Avoidant PD (%)	7.1	11.8	6.7
Borderline PD (%)	14.3	0.0	0.0
Paranoid PD (%)	7.1	0.0	0.0
Histrionic PD (%)	0.00	0.00	6.7
Obsessive-Compulsive PD (%)	42.9	0.00	20.0
Any PD (%)	50.0	17.6	26.7
Taking psychotropic meds (%)	14.3	17.6	26.7

Note. PD = personality disorder

Table 2. Means and SDs for longitudinal outcomes for all participants and broken by condition

		OQ-45	DERS	ERQ-R	WSAS
All	Intake (n = 46)	66.46 (17.70)	103.89 (24.41)	3.35 (0.81)	16.02 (6.47)
	1 week FU (n = 43)	58.74 (23.01)	88.83 (25.91)	4.67 (0.82)	12.07 (8.58)
	1 month FU (n = 42)	52.97 (22.56)	82.95 (24.99)	4.68 (0.91)	10.95 (7.20)
CR +	Intake (n = 14)	61.57 (19.77)	94.57 (26.75)	3.37 (0.94)	15.00 (7.55)
Left	1 week FU (n = 13)	59.62 (24.56)	86.92 (25.58)	4.50 (0.99)	14.31 (9.80)
rTMS	1 month FU (n = 11)	56.91 (26.30)	84.82 (33.85)	4.36 (1.12)	10.27 (7.23)
CR +	Intake (n = 17)	65.41 (18.76)	97.88 (24.36)	3.44 (0.81)	16.80 (6.53)
Right	1 week FU (n = 16)	58.00 (26.48)	80.68 (24.89)	4.80 (0.89)	10.44 (7.69)
rTMS	1 month FU (n = 17)	48.82 (23.86)	76.52 (21.09)	4.84 (0.81)	12.29 (8.85)
CR +	Intake (n = 15)	72.20 (13.44)	119.40 (13.60)	3.22 (0.73)	16.20 (5.58)
sham	1 week FU (n = 14)	58.79 (18.55)	99.93 (25.13)	4.71 (0.58)	11.86 (8.52)
rTMS	1 month FU (n = 14)	54.93 (18.24)	89.29 (20.99)	4.74 (0.84)	9.86 (4.77)
Normative data:		> 63 = clinical impairment; reliable change = 17 points	< 80 = individuals not in treatment	> 4.67 = non-clinical	10-20 clinical impairment >20 serious psychopathology

Note. FU = follow up; CR= Cognitive restructuring training and practice on autobiographical stressors. SD = standard deviation; OQ-45 = Outcome Questionnaire-45 total score; DERS = Difficulties in Emotion Regulation Scale Total Score; ERQ-R = Emotion Regulation Questionnaire- Reappraisal Scale; WSAS = Work and Social Adjustment Scale
