Abstract

The strict mathematical relationship between R_t and the curve of daily cases $f(t)$ is shown. Up to date and statistically robust R_t from the curve of daily cases can be estimated as soon as new cases are added to the curve. That is equivalent to estimating R_t by averaging all detected cases of infection, without any distortion induced by the difficulty of following and weighting trees of secondary cases from original ones, and without needing to wait for secondary cases to manifest infection. With this method, if R_t scaled numbers are of interest, only the average duration of subjects' infectivity has to be estimated directly, but independently of linking secondary cases to primary ones. A new index, *Instantaneous Reproduction Number* R_{ist} is introduced, which is mathematically tied to R_t and does not depend on the duration of infectivity of subjects. R_{ist}, R_t and the doubling/halving time of the epidemic may be estimated by simple computations at the very detection time of new daily cases. Any smoothed curve of daily cases gives smooth R_t and R_{ist}. No phase lag on R_t estimate is introduced by this method.

Motivation for this method

During the first phase of COVID19 outbreak, while tinkering with a diffusion-saturation model to fit epidemic data [7], I encountered estimations of R_t and R_0 which where incompatible with the observed doubling time of daily cases and the location in time of peaks. So, I began to think on the subject.

It seems that R_t was defined from the epidemiological point of view with the assumption in mind that an epidemic can be characterized by a somewhat stable relationship between a pathogen and its infectable host, with the intent of predicting the evolution of an outbreak. Which does not seem to work properly.

In fact, the initial susceptibility of a population of hosts is always unknown, because unknown is the reaction of the immune system spectrum and history of a population to a new pathogen or to similar ones as biochemical targets.

Besides that, both pathogen and host can have this relationship modified via several options (the decreasing susceptibility of the host population due to the spreading of the epidemic that saturates the susceptibility of a population or

sub-population; the reaction of immune systems; the reactive behaviours of host and pathogen populations; the mobility pattern of vector particles, like infecting particles in turbulent air; etc).

This writing shows how R_t definition is strictly tied to the curve of daily cases by mathematical equations. The two are essentially the same thing expressed with different words. R_t is a sort of first derivative of the curve of daily cases with respect to time t.

The difficulty of directly estimating R_t in a reliable way is the same as predicting the evolution of an epidemic in a reliable way. Indeed even much harder, since one has to face the further uncertainty of estimating and weighting trees of secondary cases implied by this process. It is very similar to estimating the space traveled by measuring acceleration with very inaccurate accelerometers, but very much harder and error prone.

The excellent articles by Cori, et al. [1] and Dietz [2] clearly show this difficulty.

Epidemiological definition of R_t

The epidemiological definition of R_t states:

> R_t *is the number of secondary infections caused by a single case of disease during its period of infectivity in a completely susceptible population, on average.*

(see: [3], [1], [2] and many other sources.)

According to this epidemiological definition, R_t is analogous to the multiplier of the initial unit capital after 1 period, in a compound capitalization process.

This analogy allows the estimation of R_t from the epidemic curve of daily cases by introducing the concept of *Instantaneous Reproduction Number R_{ist}*, similar to the instantaneous capitalization rate in actuarial mathematics.

Definition of R_{ist}

The epidemiological definition of R_t indicates an exponential expansion. So does R_0, as the limit to the beginning of an epidemic of an uninfected population. An infected individual, after his period of infectious capacity, will have infected a new infected plus (or minus) a number of new infected, on average. This is equivalent to the amount of a compound capitalization at the interest rate r, where R_t is the amount after period 1. In general:

- after period 1: $1 \cdot (1 + r) = R_t$;

- after period 2: $1 \cdot (1 + r) \cdot (1 + r) = 1 \cdot (1 + r)^2$;

- after period p: $1 \cdot (1 + r)^p$.

To obtain which interest rate r should be used for a continuous compound capitalization of n fractions of a period that gives the amount R_t after 1 period, we can write as follows:

$$R_t = \left(1 + \frac{r}{n}\right)^n \quad \text{equivalent to:} \quad R_t = \left[\left(1 + \frac{r}{n}\right)^{\frac{n}{r}}\right]^r$$

Passing to the limit for $n \to \infty$, and noting that $\lim_{n\to\infty}(1 + \frac{r}{n})^{\frac{n}{r}} = e$, we get:

$$R_t = \left[\lim_{n\to\infty}(1 + \frac{r}{n})^{\frac{n}{r}}\right]^r = e^r \quad \text{hence:} \quad r = \ln(R_t) = R_{ist} \cdot 1$$

In other terms, r is the exponent to be given to e to obtain R_t after a period of infectious duration equal to 1.

If we want to express R_{ist} in a unit of time g_i other than the dimensionless unit period, for example the days (or hours) with which we measure the duration of the infectivity period of an infectious subject and with which we measure the progress of the epidemic, we can write:

$$r = \ln(R_t) = R_{ist} \cdot g_i \quad \text{from wich:} \quad R_{ist} = \frac{\ln(R_t)}{g_i}$$

In this way we have the parameter R_{ist} which characterizes the exponential growth (as per the definition of R_t) at the point in time t that the increase (or decrease) of daily cases generates.

Connecting R_{ist} to the epidemic curve of daily cases

Whenever an exponential function $y = e^{ax}$ is represented in logarithmic scale $\ln(y) = ax$, it becomes a straight line. Its shape factor a becomes the slope of the straight line (the angular coefficient).

If we represent the curve of the daily cases $f(t)$ in logarithmic scale $h(t) = \ln(f(t))$, the slope of the tangent of $h(t)$ at point t is the slope R_{ist}, corresponding to the exponential growth of the epidemiological definition of the effective reproduction number R_t, represented in logarithmic scale, at time t, and scaled in time units of the curve of daily cases. But the tangent of $h(t)$ at point t is also the first derivative of $h(t)$. That is:

$$\frac{\ln(R_t)}{g_i} = R_{ist} = \frac{\mathrm{d}}{\mathrm{d}t}h(t)$$

A different reasoning perhaps better illustrates the concept of estimating R_t from epidemic curves.

Since all infected have been infected by someone, R_t is basically the ratio between the daily cases at time $t+1$ over the cases at time t, where 1 is the infecting period. Given the point a on the curve of daily cases that precedes the point b, then $R_t = b/a$.

Differentiating the curve of daily cases, expressed in logarithmic scale with base e, means making the difference between two values, spaced by a unitary period of time tending to zero, that is: $\ln(b) - \ln(a)$. This expression is equivalent to doing $\ln(b/a)$, as those who have used slide rules [4] easily remember: $\ln(b) - \ln(a) = \ln(b/a)$.

By doing the inverse operation of extracting a logarithm from a number, i.e. raising the base of the logarithm to a power of the value of the logarithm in question, one obtains the ratio b/a in the scale of daily cases of infection: $e^{\ln(b/a)} = b/a$.

This ratio represents the rate of increase (if > 1), or decrease (if < 1), of the infections averaged over **all** the infections observed, including **all** the information on the overall average resistance to the spread of the infection that may have formed meanwhile, for any known or unknown reason it was formed. It also takes in properly weighted account **all** the overlaps of the infection trees defined by R_t, and of the hosts' varying susceptibility.

Furthermore, the value obtained in this way is a very accurate value of R_t acting at current time of b, that is, at the very moment in which the current value of the infected cases is known. The passage to the limit of a period that tends to the instant, implicit in the differentiation operation with respect to t, allows to have a curve of R_t trend that is always updated in real-time.

According to the epidemiological definition of R_t, we have the following correspondence of classical outstanding cases, direct consequence of the epidemiological definition:

$R_{ist} > 0$: when the daily cases increase and the epidemic is expanding;
therefore the associated $e^{R_{ist} \cdot g_i} = R_t > 1$.

$R_{ist} = 0$: when the daily cases remain constant and the epidemic is stationary
therefore the associated $e^{R_{ist} \cdot g_i} = R_t = 1$.
In this case the curve of daily cases has a minimum or a maximum;
R_{ist} crosses 0; R_t crosses 1.

$R_{ist} < 0$: when the daily cases decrease and the epidemic is contracting
therefore the associated $e^{R_{ist} \cdot g_i} = R_t < 1$.

Since these outstanding cases derive from the epidemiological definition of R_t, they also are criterion for evaluating the correct estimate of R_t. A contrasting value of R_t respect to the epidemic curve is also an indication that R_t or the epidemic curve are wrong.

Summary of conversion formulas

The curve of daily cases $f(t)$ expressed in logarithmic scale with base e is obviously given by:
$$h(t) = \ln(f(t))$$

R_{ist} is given by the first derivative (numerically or analytically determined) of **any** smoothed curve of daily cases, given in logarithmic scale with base e:

$$R_{ist} = \frac{\mathrm{d}}{\mathrm{d}t} h(t)$$

Please notice that if we have a smoothing procedure of the curve of daily cases that introduces any phase lag, as we have using mobile averages or FIR/IIR filters, we will have the same phase lag in the estimation of R_{ist} and R_t. Otherwise if we have some form of static averaging, as using some least squares fitting procedure, **no phase lag is introduced**.
R_t is given by:
$$R_t = e^{(R_{ist} \cdot g_i)}$$

R_{ist} is also equivalen to:
$$R_{ist} = \frac{\ln(R_t)}{g_i}$$

The doubling or halving time of infection $g_{d \vee h}$ is given by imposing 2.0 as R_t and computing the number of resulting days (negative numbers represent halving time):

$$g_{d \vee h} = \frac{\ln(2.0)}{R_{ist}}$$

Some generable charts

The following charts show how R_t may be calculated from a fitting of the curve of cumulative cases. Obviously, the curve of daily cases is the first derivative of cumulative cases. The second derivative is the one obtained by differentiating the curve of daily cases taken in logarithmic scale to generate R_{ist}. Taken together, they form *a sort of* derivative of order 2 of the curve of cumulative cases.
The fitting is primarily done on cumulative cases because they automatically compensate some kind of errors (for example: a missed case one day may be detected

in the following days, etc.). Model and fitting techniques [7] used for the following figures are outside the scope of this writing. Here the model is simply used as source of a smoothed daily data set. The other formulas used to generate the following charts are summarized in the section above. The data source used for this fitting is the COVID-19 official one for Italy [6].

Figure 1. a) Data fit with an adaptive diffusion-saturation model on cumulative cases. b) Daily cases smoothed by fitting, in logarithmic scale with base e used for generating R_t and R_{ist}. (Model and fitting techniques used for these charts are outside the scope of this writing. Data source: [6]. Fitting model and details: [7])

Conclusion

Reproduction number R_t and *epidemic curve of daily cases* are essentially the same thing expressed with different words. The conversion formulas between the two are shown.

The strict mathematical relationship between the *Reproduction Number R_t* and the *epidemic curve of daily cases* allows to substitute complex and error prone statistical estimations with deterministic computations from the count of daily cases. It is still necessary to directly estimate the average duration of the infectivity of subjects, but independently of linking secondary cases to primary ones. Moreover, the obtained estimation of R_t is done averaging all detected cases, instead of a possibly deviated sample of them..

The method also completely eliminates, by mathematics, the uncertainty introduced by the process of identifying secondary cases from primary ones along

overlapping trees of infectious relationships. Since all detected daily cases are infected by someone, the resulting curve of daily cases is the perfectly balanced action of R_t, and it is detected in full. This method automatically incorporates that balance.

Also, the R_t estimate performed by this method is always up to date, as soon as new cases are added to the epidemic curve, without the need to wait for secondary cases to manifest after the period of infection.

Just a glance at the dispersion of an ample set of daily data around a good fitting of these data let easily imagine how difficult and unreliable could be any attempt to directly estimate a trend of the epidemic from small samples of cases and relying on considerations of the spread of these samples over overlapping trees of secondary cases. But this is exactly what the epidemiological definition of R_t asks to do.

A more general conclusion may be drawn by observing how different is the evolution of an epidemic of the same pathogens in different regions or times. The ample difference of R_t curves computed by this method on different zones [8] clearly shows that the dynamics of an epidemic seems to follow unpredictable and chaotic behavior, very much like weather.

We are used to think of populations involved in an epidemic as an isotropic material, like steel, which has equal behavior in all directions respect to stress and strain. SIR models and the epidemiological definition of R_t seem to implicitly assume this isotropy.

Perhaps, an epidemic may better be depicted as acting on many different relationship's fabrics entangled together. A burst of infections occurs when two or more entangled fabrics mix and new connections merge in a new more extended fabrics–entangled fabrics which may be some in a stable infectious condition that eventually becomes saturated, and others not.

If this is a plausible landscape of a population's infection, not every link in this entanglement of networks has the same infection capacity and not all nodes of these networks are isotropically connected.

In other words, there may be several networks that may have poor connections with each other, while having strong connection among the members of each network. For example, the network of families with children that go to the same school may have strong links between families of teachers and classmates, but may have weak connections with other unrelated networks of parents-children-teachers. Some of these networks may saturate eventually, while others may not have even been infected. The same thing happens with other types of relational networks. This is a very anisotropic environment.

This landscape shows a very challenging non linear object to investigate. Maybe, it has some emerging regularities at the macroscopic level, like sequences of overlapping sigmoidal shapes in the curve of cumulative cases, just as a complex sound emerges from the combination of elementary sinusoids. World [5] and regional [8] COVID-19 data of cumulative cases show everywhere overlapping sigmoids.

Maybe sophisticated tools, like the emerging field of "dynamical networks", will provide interesting insights. However, to build reliable models based on the dynamics of networks is very difficult. The risk always is that the model needs a one-to-one mapping to the unknown phenomenon object of modelling, which leads to the conclusion that the proof may only be in the pudding.

Acknowledgments

Thanks to all those who taught me some mathematics and computing. Special thanks to prof. Roberto Merletti, prof. Giorgio Palù, prof. Fabio Truc, dr. Aldo Gotta, prof. Giulio Tarro and prof. Federico Butera who appreciated this work at various stages of development.
