Abstract

Background

Vaccines remain the cornerstone for containing the SARS-CoV-2 pandemic. mRNA vaccines provide protection in clinical trials using a two-dose approach, separated by a three to four week gap. UK policy in 2021 is to extend the dosing interval from three to twelve weeks. There is a paucity of data in the elderly, even though these individuals are the first to receive vaccines due to risk of severe disease. Here we assessed real world immune responses following vaccination with mRNA-based vaccine BNT162b2.

Methods:

We did a prospective cohort study of individuals presenting for first dose vaccination. Following the first and second doses of the BNT162b2 vaccine, we measured IFNγ T cell responses, as well as binding antibody (IgA, IgG and IgG1-4) responses to Spike and Spike RBD. We also measured serum neutralising antibody responses to wild type (Wuhan with D614G) and B.1.1.7 Spike using a lentiviral pseudotyping system. We correlated age with immune responses and compared responses after the first and second doses.

Results

Median age was 81years amongst 50 participants after the first dose of the BNT162b2 vaccine. Geometric mean neutralisation titres in participants over 80 years old after the first dose were lower than in younger individuals [79.9 (95%CI 35.9-177.6) vs 19.0 (10.7-33.8) p<0.01]. A lower proportion of participants 80 years and older achieved adequate neutralisation titre of >1:20 for 50% neutralisation as compared to those under 80 (11/26 versus 19/24, p<0.01). Binding IgG1 responses correlated with neutralisation, though IgG2-4 responses did not. Sera from participants in both age groups showed lower, though not statistically significant, neutralisation potency against B.1.1.7 Spike pseudotyped viruses as compared to wild type. SARS-CoV-2 Spike specific T- cell responses were similar across age groups and increased between vaccine doses. Following the second dose, 50% neutralising antibody titres were above 1:20 in all individuals and there was no longer a difference by age grouping.

Conclusions

There was a significantly higher risk of a suboptimal neutralising antibody response following first dose vaccination with BNT162b2 in those above the age of 80, cautioning against extending the dosing interval in this high risk population.

Background

Vaccines designed to elicit protective immune responses remain the key hope for containing the SARS-CoV-2 pandemic. In particular, mRNA vaccines have shown promise in clinical trials and have used a two-dose approach, separated by a three or four week gap[1,2]. However, duration of protection is not known and clinical trials provide few data on neutralising responses or efficacy in individuals above the age of 80. For example there were only twelve patients above the age of 65 evaluated for neutralising responses in a Pfizer vaccine study[3]. This is pertinent for settings where a dosing interval of twelve instead of three weeks is currently being used to maximise first dose administration[4]. Data on vaccine responses are vital in order to understand the efficacy of vaccination using this regime, particularly in groups under-represented in clinical trials, such as those aged above 80 years who are at greatest risk of severe disease and death[5]. In the UK, the government targeted this age group for access to the first vaccine available, BNT162b2. However, some weeks later the decision was made to extend the dosing schedule from 3 to 12 weeks, in order to vaccinate a greater proportion of the population during a period of substantial transmission. Other countries have been considering similar strategies.

Here we assessed real world immune responses following vaccination with mRNA-based vaccine BNT162b2[1] in unselected elderly participants from the community and younger health care workers. During the study, the vaccination was initially given under the manufacturer recommended schedule based on two-doses with a three week interval. This was then changed following recommendation by the UK Joint Committee on Vaccination and Immunisation (JCVI) to a dosing interval of 12 weeks[6]. We measured T cell responses to SARS-CoV-2 peptides by IFNγ FluoroSpot, serum IgG and IgA Spike antibodies, IgG subclasses 1-4, and serum neutralising antibody responses following the first and second doses of the BNT162b2 vaccine.

Methods

Study Design

Community participants or health care workers receiving the first dose of the BNT162b2 vaccine between the 9th of December 2020 to the 3rd of February 2021 were consecutively recruited at Addenbrookes Hospital into the COVID-19 cohort of the NIHR Bioresource. Participants were followed up for up to 3 weeks after receiving their second dose of the BNT162b2 vaccine. They provided blood samples 3 to 9 weeks after their first dose and again 3 weeks after the second dose of the vaccine. Consecutive participants were eligible without exclusion. The exposure of interest was age, categorised into 2 exposure levels- < 80 and ≥ 80 years. The outcome of interest was inadequate vaccine-elicited serum antibody neutralisation activity at least 3 weeks after the first dose. This was measured as a dilution of serum required to inhibit infection by 50% (ID50) in an *in vitro* neutralistion assay. An ID50 of 20 or below was deemed as inadequate neutralisation. Binding antibody responses to Spike protein as measured by multiplex particle-based flow cytometry and T cell responses measured by IFNγ FLUOROSPOT assays were exploratory outcomes.

We assumed a risk ratio of non-neutralisation in the ≥80 years group compared with <80 years group of 5. Using an alpha of 0.05 and power of 90% required a sample size of 50 with a 1:1 ratio in each group.

Ethical approval

The study was approved by the East of England – Cambridge Central Research Ethics Committee (17/EE/0025).

Statistical Analyses

Descriptive analyses of demographic and clinical data are presented as median and interquartile range (IQR) when continuous and as frequency and proportion (%) when categorical. The difference in continuous and categorical data were tested using Wilcoxon rank sum and Chi-square test respectively. Logistic regression was used to model the association between age and the neutralisation by vaccine-elicited antibodies after the first dose of the BNT162b2 vaccine. The effect of age as a confounder was adjusted for. Linear regression was also used to explore the association between age, ID50, binding antibody levels, antibody subclass levels and T cell response after dose 1 and dose 2 of the BNT162b2 vaccine. The Pearson correlation coefficient was reported. Statistical analyses was done using Stata v13 and Prism v9.

Generation of Mutants and pseudotyped viruses

Wild-type (WT) bearing 614G and B.1.1.7 bearing mutations del-69/70, del-144, N501Y, A570D, D614G, P681H, S982A, T716I and D1118H or K417N, E484K and N501Y pseudotyped viruses were generated as previously described[7]. In brief, amino acid substitutions were introduced into the D614G pCDNA_SARS-CoV-2_S plasmid as previously described[8] using the QuikChange Lightening Site-Directed Mutagenesis kit, following the manufacturer's instructions (Agilent Technologies, Inc., Santa Clara, CA). Sequences were verified by Sanger sequencing. The pseudoviruses were generated in a triple plasmid transfection system whereby the Spike expressing plasmid along with a lentviral packaging vector- p8.9 and luciferase expression vector- psCSFLW where transfected into 293T cells with Fugene HD transfection reagent (Promega). The viruses were harvested after 48 hours and stored at -80oC. TCID50 was determined by titration of the viruses on 293Ts expressing ACE-2 and TMPRSS2.

Neutralisation assays

Spike pseudotype assays have been shown to have similar characteristics as neutralisation testing using fully infectious wild type SARS-CoV-2[9]. Virus neutralisation assays were performed on 293T cell transiently transfected with ACE2 and TMPRSS2 using SARS-CoV-2 Spike pseudotyped virus expressing luciferase[10]. Pseudotyped virus was incubated with serial dilution of heat inactivated human serum samples or sera from vaccinees in duplicate for 1h at 37˚C. Virus and cell only controls were also included. Then, freshly trypsinized 293T ACE2/TMPRSS2 expressing cells were added to each well. Following 48h incubation in a 5% CO_2 environment at 37°C, luminescence was measured using the Steady-Glo Luciferase assay system (Promega). Neutralization was calculated relative to virus only controls. Dilution curves were presented as a mean neutralization with standard error of the mean (SEM). 50% neutralization- ID50 values were calculated in GraphPad Prism. The limit of detection for 50% neutralisation was set at an ID50 of 20. The ID50 within groups were summarised as a geometric mean titre (GMT) and statistical comparison between groups were made with Mann-Whitney or Wilxocon ranked sign test.

SARS-CoV-2 serology by multiplex particle-based flow cytometry (Luminex):

Recombinant SARS-CoV-2 N, S and RBD were covalently coupled to distinct carboxylated bead sets (Luminex; Netherlands) to form a 3-plex and analyzed as previously described[11]. Specific binding was reported as mean fluorescence intensities (MFI).

IFNγ FLUOROSPOT assays

Frozen PBMCs were rapidly thawed, and the freezing medium was diluted into 10ml of TexMACS media (Miltenyi Biotech), centrifuged and resuspended in 10ml of fresh media with 10U/ml DNase (Benzonase, Merck-Millipore via Sigma-Aldrich), PBMCs were incubated at 37°C for 1h, followed by centrifugation and resuspension in fresh media supplemented with 5% Human AB serum (Sigma Aldrich) before being counted. PBMCs were stained with 2ul of each antibody: anti-CD3-fluorescein isothiocyanate (FITC), clone UCHT1; anti-CD4-phycoerythrin (PE), clone RPA-T4; anti-CD8a-peridinin-chlorophyll protein - cyanine 5.5 (PerCP Cy5.5), clone RPA-8a (all BioLegend, London, UK), LIVE/DEAD Fixable Far Red Dead Cell Stain Kit (Thermo Fisher Scientific). PBMC phenotyping was performed on the BD Accuri C6 flow cytometer. Data were analysed with FlowJo v10 (Becton Dickinson, Wokingham, UK). 1.0 to 2.5 x 105 PBMCs were incubated in pre-coated Fluorospot plates (Human IFNγ FLUOROSPOT (Mabtech AB, Nacka Strand, Sweden)) in triplicate with peptide mixes specific for Spike, Nucleocapsid and Membrane proteins of SARS-CoV-2 (final peptide concentration 1µg/ml/peptide, Miltenyi Biotech) and an unstimulated and positive control mix (containing anti-CD3 (Mabtech AB), Staphylococcus Enterotoxin B (SEB), Phytohaemagglutinin (PHA) (all Sigma Aldrich)) at 37ºC in a humidified CO_2 atmosphere for 48 hours. The cells and medium were decanted from the plate and the assay developed following the manufacturer's instructions. Developed plates were read using an AID iSpot reader (Oxford Biosystems, Oxford, UK) and counted using AID EliSpot v7 software (Autoimmun Diagnostika GmbH, Strasberg, Germany). All data were then corrected for background cytokine production and expressed as SFU/Million PBMC or CD3 T cells.

Results

Fifty-one participants received at least one vaccination, with median age 81years (IQR 81-84) and 33% of participants being female (Table 1). Sera from vaccinated individuals exhibited an increase in neutralising titres against pseudoviruses expressing wild-type SARS-CoV-2

Spike protein between the first and second doses (Figure 1A, B). Geometric mean neutralisation titre after the first dose was lower in participants 80 years and older than in younger individuals [79.9 (95%CI 35.9-177.6) vs 19.0 (10.7-33.8), p<0.01 Table 1, Figure 1C]. A lower proportion of participants over 80 years old achieved adequate neutralisation titre of >1:20 for 50% neutralisation as compared to those under 80 (11/26 versus 21/24, p<0.001).

Age showed statistically significant correlation with serum neutralisation of WT virus after the first but not second dose (Figure 1D, E). In those participants with suboptimal neutralisation (examples shown in Figure 1F), re-testing three weeks after the second dose showed that all responded, with neutralisation activity comparable to those who responded well to the first dose (Table 1 and Figure 1C).

Binding antibody responses to the wild type Spike were comprehensively measured using a particle based assay. IgA responses were detected both in convalescent sera and after both doses, with small increase between the two time points (Figure 2A). All IgG subclasses against Spike and RBD increased between vaccine doses (Figure 2B), as is observed in cases of natural infection. IgG1 concentrations were significantly lower in the >80 age group (Figure 2D) and IgG1 showed significant correlation with age in contrast to IgG2-4 (Supplementary Figure 1A). Spike specific IgA and IgG levels after dose 1 correlated with neutralisation (Figure 2C). More specifically, serum IgG1 responses to Spike correlated significantly with neutralisation, though IgG2-4 responses did not (Supplementary Figure 1B).

CD3+ T cells were stimulated with overlapping peptide pools to the wild type SARS-CoV-2 Spike in addition to Cytomegalovirus, EBV and Flu (CEF+) peptide pools in an IFNγ FluoroSpot assay to enumerate spike specific T cells. Following the first dose of vaccine only 2/27 participants had no detectable spike specific T cells (Figure 3A); of the remainder the average response was 106 SFU/million CD3+ T cells and median 55.1 (range 8.5-586). However, there was no statistical difference in responses between <80 and >80 years of age groups (Figure 3B, Supplementary Figure 2). Following the second dose only 1/20 individuals had no detectable spike specific T cells (Figure 3A). That participant did not have a detectable response following the first dose; of the remainder the average response was 598

SFU/million CD3+ T cells and median 320 (range 29.6-5811), a statistically significant increase from first to second dose (Figure 2A). Similar to the first dose, second dose T cell responses showed no statistical difference between <80 and >80 year groups (Figure 2B, Supplementary Figure 2). As expected, T cell responses to positive control stimulations and responses to CEF+ peptide stimulation were overlapping between dose 1 and 2 (Figure 2 B, Supplementary Figure 2). Sixteen of the 20 participants tested following a second dose had increased T cell responses, with variable fold change between participants. CD3+ T cell responses did not correlate with serum neutralisation after either dose (Figure 3C, 3D).

Given our observation that the participants 80 years old and older had lower neutralisation responses following first dose, we hypothesised that this would be exacerbated by the B.1.1.7 variant. We therefore examined serum neutralisation by age group against WT or the B.1.1.7 spike variant after the first dose (Figure 4). The adjusted odds ratio for achieving inadequate neutralisation against WT was 9.5 (2.3-40.2, p0.002) for participants 80 years old and older versus those younger than 80 (Table 2). The adjusted odds ratio for inadequate neutralisation activity against the B.1.1.7 variant was 12.2 (3.1-48.9, p<0.001) (Table 2).

Discussion

Here we have addressed an important aspect of rollout of vaccination against SARS-CoV-2, where the second dose may be delayed due to supply limitations. We have shown that around half of individuals above the age of 80 have a suboptimal neutralising antibody response at least three weeks after vaccination with BNT162b2, associated with lower IgG1 concentrations. The second dose is associated with robust neutralising responses across all age groups. Binding IgA antibodies to Spike and RBD increased following the first and second doses, mirroring levels seen in natural infection. IgG3 responses to Spike and RBD increased predominantly after the second dose. Spike specific T cell responses, measured by IFNγ secretion, were also significantly lower in the over 80 age group. As expected from previous studies[7,12], sera from participants in both age groupings indicated modestly lower neutralisation potency against B.1.1.7 Spike pseudotyped viruses as compared to wild type. Consistent with this a greater proportion of individuals in the over 80 age group moved into the poor neutralisation category following first dose when considering B.1.1.7 (72.0% versus 57.7%).

In a clinical study specifically looking at older adults vaccinated with BNT162b2 the GMT (geometric mean titre) after first dose was 12 in a set of 12 subjects between ages of 65 and 85 years, rising to 149 seven days after the second dose [3]. Furthermore, in the Moderna 1273 mRNA vaccine study in older individuals (above 55 years), neutralisation was only detectable after the second dose, whilst binding antibodies were detectable after both doses[13].

Immune senescence is a well described phenomenon whereby responses to pathogens[14] and indeed vaccines are impaired/dysregulated with age[15]. As an example, effective seasonal influenza vaccination of the elderly is a significant public health challenge due to greater morbidity and mortality in this group. Lower neutralizing antibody titres using standard dose influenza vaccines in elderly individuals has been addressed by using higher dose vaccine [16]. As such it is not surprising that while a single dose of BNT162b2 failed to induce neutralizing antibodies in a proportion of participants, a second dose 3 weeks later resulted in all participants mounting a neutralizing antibody response. In aged mice the ChAdOx nCov-19 vaccine responses were reported as being lower as compared to younger mice, and this was overcome by booster dosing[17]. Importantly the UK REACT study, an observational community based study, has shown that the prevalence of IgG positivity was 34.7% 21 days after the first dose of BNT162b2 in those over 80 years[18]. Similarly, REACT reported that IgG positivity increased to 87.8% after the second dose. Although it remains unclear how this will translate into protection from COVID-19, it raises concerns about if those over 80 years will be adequately protected with one dose.

IgG3 has been reported to be dominant following natural SARS-CoV-2 infections, unlike the IgG1 dominance seen in other respiratory viral infections[19,20]. While IgG1 and IgG3 are both commonly induced by viral infection and associated with neutralization there is data suggesting IgG1 plays a lead role in neutralization of Influenza[19], West Nile virus[21] and HIV[22]. Interestingly, despite the dominance of IgG3 in SARS-CoV-2 infection, we observed a correlation between IgG1 and neutralization titres suggesting this is the major neutralizing subclass following vaccination.

The low IgG1 and neutralisation data may be attributable to immunoscenence in around half of over 80 year olds in this study. Immunosenescence may also be reflected in participants below 80, a minority of whom showed poor responses. Importantly, our data are relevant to the significant proportions of younger adults with immune dysfunction due to primary or

secondary immune deficiency. Given the variability in neutralising responses and the data relating neutralisation activity with protection from infection that are emerging, it seems prudent to plan testing strategies aimed at identification of suboptimal responses in order to prioritise individuals to receive the second dose on time and possibly to guide boosting.

The ChAdOx nCov-19 vaccine was reported as being effective even with a twelve week gap between the two doses[23]. However, this study was in younger individuals, and would be consistent with neutralising responses in those under 80 in our study. It is possible that the suboptimal responses we observed may improve after 3 weeks in older individuals. Even if this is the case, individuals over 80 are nonetheless likely to be at prolonged increased risk for infection, based on studies in non-human primates linking protection from SARS-CoV-2 challenge with neutralising antibody titres, but not T cell responses [24,25]. In further support for the role of neutralising antibodies are two clinical studies: (i) use of early convalescent sera in COVID-19 disease within elderly patients demonstrating improved clinical outcomes[26] and (ii) the recent report of suboptimal efficacy of the ChAdOx nCov-19 vaccine against prevention of mild to moderate COVID-19 in the context of the variant 501Y.V2[27]. Although the second dose was able to boost neutralising antibodies, SARS-CoV-2 infection during an enlarged window period between doses in the presence of only partially protective antibody titres could also lead to favourable conditions for selecting escape mutations[8,28]. It therefore will be important to follow all participants over the following months to measure the kinetics of neutralisation activity as well as to gather data on re-infection. The arrival of new variants with the potential to compromise vaccines[29-32] may mandate regular re-vaccination with modified vaccine preparations.

Limitations

We were not able to ascertain prior infection in our participants. However, the lack of neutralisation and low antibody levels following vaccination in a significant proportion of the over 80 group argues against prior infection in the poor responders. We were also unable to adjust for confounders such as immune suppression and comorbidities as these data were not collected. They may also be other unmeasured confounders that may modify the association between age and neutralisation status. However, consecutive participants were recruited without exclusion. Although participant numbers were modest our sample size estimation suggest we recruited sufficient participants to limit type I error. In addition, the numbers of

elderly participants undergoing assessment for neutralisation and T cell responses was greater than manufacturer-sponsored vaccine studies[3, 9].

Conclusion

Whilst significant public health impact of vaccines is anticipated, and indeed has been demonstrated after the first dose[33], a significant proportion of individuals above 80 appear to require the second dose to achieve in vitro virus neutralisation. Our data caution against extending the dosing interval of BNT162b2 in the elderly population, particularly during periods of high transmission, where there is the added risk from variants that are less susceptible to vaccine-elicited neutralising antibodies[7,29,30,32]. If rapid antibody tests are able to differentiate those in risk groups who have satisfactory neutralisation responses then a widened dosing interval may be appropriate under certain circumstances.

Figure 1

Figure 1. A-C. Neutralisation by Pfizer BNT162b2 vaccine sera against SARS-CoV-2 in a Spike lentiviral pseudotyping assay expressing wild type Spike (D614G). Data are shown as mean ID50 values for individuals three weeks after Dose 1 (n=50) and three weeks after Dose 2 (n=21). Geometric mean with standard error is shown. Each point is a mean of technical replicates from two experiment repeats. **D, E.** Correlation between serum neutralisation of Spike (D614G) pseudotyped lentiviral particles (inhibitory dilution at which 50% inhibition of infection is achieved, ID50)and age after the first dose (D) and the second dose (E) of Pfizer BNT162b2 vaccine. **F.** Neutralisation curves for serum from six individuals with reduced responses after first dose of Pfizer BNT162b2 vaccine against pseudovirus expressing wild type Spike (D614G). Means of technical replicates are plotted with error bars representing standard error of mean. Data are representative of 2 independent experiments. Mann-whitney test was used for unpaired comparisons and Wilcoxon matched-pairs signed rank test for paired comparisons. p-values * <0.05, ** <0.01, **** <0.0001, ns not significant, HS – human AB serum control, r– Pearson's correlation coefficient, β slope/regression coefficient.

Figure 2

Figure 2: Binding antibody responses following vaccination with Pfizer BNT162b2 vaccine. Dose 1 n=25, dose 2 n=21. A. IgA responses to S, N, RBD post first (light green) and second dose (dark green) compared to individuals with prior infection(red) and negative controls (grey) across serum dilutions. **B,C.** Correlations between binding antibody responses and neutralisation by vaccine sera against SARS-CoV-2 in a Spike lentiviral pseudotyping assay expressing wild type Spike (D614G) **D.** IgG subclass responses to S, N, RBD post first and second dose compared to individuals with prior infection. **E.** Anti-Spike IgG- total and subclasses after first dose of vaccine stratified by age < and >80 years old. MFI – mean fluorescence intensity. S – Spike, N – nucleocapsid, RBD – Spike receptor binding domain. Mann-whitney test was used for unpaired comparisons. p-values * <0.05, *** <0.001, ns- not significant HS – human AB serum control, r– Pearson's correlation coefficient, p- P value, β slope/regression coefficient.

Figure 3

Figure 3: T cell responses to Pfizer BNT162b2 vaccine after the first and second doses of Pfizer BNT162b2 vaccine. Dose 1 n=27, dose 2 n=21. A. FluoroSpot interferon gamma T cell responses to SARS-CoV-2 peptide pool three weeks after the first and three weeks after second doses of Pfizer BNT162b2 vaccine. **B.** FluoroSpot IFNγ T cell responses stratified by age <>80 years old. Also shown are positive control (PHA), CEF peptide pool (comprising peptides from influenza, CMV, EBV SARS-CoV-2). **C. D**. Correlation between serum neutralisation of Spike (D614G) pseudotyped lentiviral particles (inhibitory dilution at which 50% inhibition of infection is achieved, ID50) and T cell responses against SARS-CoV-2 by IFNγ FluoroSpot after first (C) and second (D) dose. SFU: spot forming units. r: pearson correlation coefficient with p value indicated and b the slope coefficient. Mann-whitney test was used for unpaired comparisons and Wilcoxon matched-pairs signed rank test for paired comparisons. p-values ** <0.01, *** <0.001, ns not significant.

Figure 4

Figure 4 Neutralization by first dose Pfizer BNT162b2 vaccine sera against wild type and B.1.1.7 Spike mutant SARS-CoV-2 pseudotyped viruses. Shown on y axis is GMT against WT (D614G) and B.1.1.7 Spike mutant with N501Y, A570D, ΔH69/V70, Δ144/145, P681H, T716I, S982A and D1118H. GMT with s.d presented of two independent experiments each with two technical repeats. Limit of detection for 50% neutralization set at 20. GMT: geometric mean titre for 50% neutralization. Mann-whitney test was used for unpaired comparisons and Wilcoxon matched-pairs signed rank test for paired comparisons. p-values *** <0.001, **** <0.0001, ns not significant.

Supplementary Figure 1. A. Correlations between serum binding IgG subclass 1-4 antibody responses following vaccination with first dose of Pfizer BNT162b2 vaccine and age in years. **B.** Correlations between serum binding IgG subclass 1-4 antibody responses following vaccination with first dose of Pfizer BNT162b2 vaccine and serum neutralization using a pseudotyped viral system. MFI- mean flourescence intensity ID50 – inhibitory dilution required to achieve 50% inhibition of viral infection. r pearson's correlation coefficient, β slope/regression coefficient.

Supplementary Figure 2. FluoroSpot interferon gamma PBMC responses to SARS-CoV-2 peptide pool three weeks after the first and three weeks after second doses of Pfizer BNT162b2 vaccine. Also shown are positive control (PHA) and CEF peptide pool (comprising peptides from influenza, CMV, EBV SARS-CoV-2). Mann-whitney test was used for unpaired comparisons and Wilcoxon matched-pairs signed rank test for paired comparisons. p-values * <0.05, *** <0.0001, ns not significant
