Running title: Antibiotics and hospital-associated *Clostridioides difficile* infection.

Funding: This study did not receive any external funding.

Transparency declarations: All authors have no conflicts to declare in relation to this work.

Abstract

Background: *Clostridioides difficile* infection (CDI) is the most common cause of healthcare facility-associated (HCFA) infectious diarrhoea in high-income countries. Antibiotic use is the most important modifiable risk factor for CDI. The most recent systematic review covered studies published until 31st December 2012.

Objectives: To update the evidence for epidemiological associations between specific antibiotic classes and HCFA-CDI for the period 1st January 2013 to 31st December 2020.

Data sources: PubMed, Scopus, Web of Science Core Collection, WorldCat, and Proquest Dissertations and Theses.

Study eligibility criteria, participants and exposures: Eligible studies were those conducted among adult hospital inpatients, measured exposure to individual antibiotics or antibiotic classes, included a comparison group, and measured the occurrence of HCFA-CDI as an outcome.

Study appraisal and synthesis methods: The Newcastle–Ottawa Scale for the Assessment of Quality was used to appraise study quality. To assess the association between each antibiotic class and HA-CDI, a pooled random effects meta-analysis was undertaken. Metaregression and sub-group analysis was used to investigate study characteristics identified *a priori* as potential sources of heterogeneity.

Results: Carbapenems, and 3rd and 4th generation cephalosporin antibiotics remain most strongly associated with HCFA-CDI, with cases more than twice as likely to have recent exposure to these antibiotics prior to developing CDI. Modest associations were observed for fluoroquinolones clindamycin, and beta-lactamase inhibitor combination penicillin antibiotics.

Limitations: Individual study effect sizes were variable and heterogeneity was observed for most antibiotic classes. Availability of a single reviewer to select, extract and critically appraise the studies.

Conclusions: This review provides the most up to date synthesis of evidence in relation to the risk of HCFA-CDI associated with exposure to specific antibiotic classes. Studies were predominantly conducted in North America or Europe and more studies outside of these settings are needed.

Registration number: Prospero CRD42020181817

Introduction

Clostridioides difficile infection (CDI) is a leading cause of healthcare-associated infections and the most common cause of health care facility-associated (HCF) infectious diarrhoea in high-income countries. ¹ *C. difficile* is a toxin-producing, anaerobic spore forming bacterium that is transmitted via the faecal-oral route. ² Symptoms range from mild diarrhoea to life-threatening conditions such as pseudomembranous colitis and toxic megacolon, and recurrence occurs among approximately 20% of cases following an initial episode. ² CDI is associated with a protracted length of stay incurring substantial direct and indirect healthcare utilisation costs. ³⁻⁵ Incidence rates of healthcare facility-associated (HCFA) CDI are geographically and temporally variable but have generally increased in the past 20 years. ^{1, 6, 7} Explanations for the increasing occurrence include increased testing and more sensitive diagnostic tests, increased use of broad-spectrum antibiotics, inadequate prevention measures, ageing population and emergence of community strains. ⁷

Antibiotic use is the most important modifiable risk factor for CDI. Antibiotic exposure alters the natural flora of the intestines allowing *C. difficile* to proliferate. Other important risk factors include advanced age, increased number of comorbidities or severe underlying disease, and duration of healthcare exposure. ^{8, 9} A longer duration of hospitalisation is correlated with advanced age and severity of underlying illness, and increases the probability of *C. difficile* acquisition from the environment and exposure to antibiotics. Although almost all antibiotics have been associated with CDI, clindamycin, cephalosporins, carbapenems and fluoroquinolones are most frequently associated with infection. ^{10, 11}

Antibiotic stewardship reduces unnecessary antibiotic use in hospitals ¹² and is crucial to controlling CDI in HCFs alongside surveillance, isolation precautions, hand hygiene and environmental cleaning. ^{8, 13} Limiting antibiotic use effectively reduces the incidence of CDI in HCFs, ¹⁴ however, CDI remains a significant problem and has been named by the US Centers for Disease Control as an urgent threat to public health. ¹⁵

It is therefore important to monitor changes in risk for HCFA-CDI associated with changes in antibiotic usage and changing *C. difficile* epidemiology. The objective of this systematic review is to update the evidence for epidemiological associations between specific antibiotic classes and HCFA-CDI. This review updates earlier reviews that covered studies conducted up to 2012, ^{10, 11} to include studies undertaken between 2013 and 2020.

Methods

The study has been conducted in accordance with the PRISMA statement. ¹⁶ The objectives, inclusion criteria and methods for analysis were specified in advance and registered with PROSPERO (CRD42020181817).

Eligibility criteria

Studies were eligible for inclusion in the review if they were conducted among hospital inpatients, measured any exposure to individual antibiotics or antibiotic classes prior to development of the outcome, included a comparison group, and measured the occurrence of HA-CDI as an outcome. Study designs eligible for inclusion consisted of case-control studies, cohort studies, analytical cross-sectional studies and randomised controlled trials (if they reported the risk associated with the exposure).

Studies were excluded if they investigated risk factors for severe disease, relapse or recurrence, asymptomatic colonisation, or were specific studies of paediatric populations. Studies that did not

report exposure to specific antibiotics or antibiotic classes were also excluded, as were studies examining community associated infection or did not adequately exclude CA. Case reports, case series, and descriptive cross-sectional studies (i.e. those without comparison groups) were excluded. The review was limited to English-language publications, however, non-English articles were included in searches and their abstracts and full texts were assessed for eligibility.

Information sources and searching

PubMed, Scopus and Web of Science Core Collection were searched on 21st April 2020 for studies published since 1st January 2013. WorldCat (www.worldcat.org) and Proquest Dissertations and Theses (PQDT www.proquest.com) were used to search for dissertations and theses. Final follow up searches to 31st December 2020 were conducted on 11th February 2021.

The search strategy used was consistent with the previous review.¹⁰ The full search strategy for each database presented in the Supplementary file. Search results were exported to Endnote X9.1, which was used to identify and remove duplicates prior to importing to Covidence (www.covidence.org) for title and abstract screening.

Study selection

Titles and abstracts were screened to eliminate irrelevant studies. Full text articles were then inspected for eligibility. Studies were classified as confirmed HCFA-CDI if they included a clear definition of HCFA-acquisition of CDI, or probable HCFA-CDI on the basis of information provided in the report, e.g. evidence that the minimum length of stay until onset of symptoms was >48 hours. Studies that had been excluded from the previous review because they did not use an explicit definition of HA were re-evaluated and subsequently included in this review if there was sufficient evidence that HA-CDI was probable.

Data collection

Data were extracted from each study using a pro forma template that included the study characteristics (citation, country, setting, study period based on earliest time point, study population, study design, HCFA-CDI case and non-case definitions, antibiotic name, exposure period and timing, comparison group), number of subjects in exposure categories for cases and non-cases, effect estimates (odds ratio; relative risk) and 95% confidence intervals.

Antibiotic exposures were categorised into their main classes with additional sub-group categorisation for cephalosporins (1st, 2nd, 3rd, 4th generation), penicillins (ampicillin-like drugs [aminopenicillins]; beta-lactamase inhibitor combinations; broad-spectrum [antipseudomonal] penicillins; penicillin G-like drugs [natural penicillins]) using the MSD Manual.¹⁷ The unexposed comparator groups were categorised as no antibiotics; unexposed to antibiotic of interest; a reference antibiotic. The exposure period was classified in two ways. First, whether antibiotic administration before CDI diagnosis was recorded by the study and, second, the period of time over which antibiotic administration was measured and categorised as: during index admission; up to 1 month prior to CDI diagnosis; up to 1-2 months prior; up to 2-3 months prior; preoperative prophylaxis; during admission - prior to ICU; during ICU admission.

The non-CDI case groups were recorded as asymptomatic or symptomatic (patients had diarrhoea but tested negative for *C. difficile*). Study setting was classified according to geographic region (North America, Latin America, Europe, East Asia & Pacific) and patient population: general adult inpatients and specific clinical sub-groups (HA-pneumonia, HA-diarrhoea, antibiotic treatment, ICU

patients, COPD patients, *C. difficile* colonised, haematology-oncology patients, surgical – gastrointestinal, surgical – non-gastrointestinal, type 2 diabetes).

Assessment of methodological quality

The Newcastle–Ottawa Scale for the Assessment of Quality (NOS) was used to assess study quality.¹⁸ The NOS comprises nine items across the domains of: selection, comparability, and exposure (case-control studies) or outcome (cohort studies). Each accomplished item receives one point and studies are classified as high quality (score 7–9), moderate quality (score 4–6), or poor quality (score 0–3). Important confounding domains considered in the study for assessment of comparability were identified from previous studies and included: age, comorbidities, severity of underlying disease (1 point), and healthcare facility exposure or other treatment (1 point)⁹. Poor quality studies were not excluded from the review, instead overall study quality and level of comparability were explored as potential sources of heterogeneity.

Analysis

Data were entered into Excel for coding and exported to Stata version 14 for analysis. A quantitative descriptive analysis summarising the characteristics of included studies was undertaken, presented as counts and percentages.

To assess the association between each antibiotic class and HA-CDI, a pooled random effects analysis using the DerSimonian-Laird inverse variance approach was used.^{19,20} The meta-analysis was restricted to studies that used a comparison group that was unexposed to the antibiotic of interest, as this was the comparison used in most studies. As most studies reported odds ratios (OR), the most fully adjusted odds ratio was used for synthesis. Where studies reported results for multiple antibiotics within each class, without providing the relevant overall association for that class, effect estimates were combined by taking the weighted average of the log ORs, with inverse variance weights. Heterogeneity of pooled effects was assessed using the I^2 statistic, which describes the percentage of variability in the effect estimates that is due to heterogeneity rather than chance, and its chi-squared statistic for evidence of heterogeneity ($p < 0.10$).

A sub-group analysis was used to assess study characteristics identified *a priori* based on previous findings as sources of heterogeneity. Specific characteristics investigated included setting (geographic region, time period when the study was conducted, patient population), exposure measurement (time period prior to CDI diagnosis, measurement after onset), and methodology (study design, HA definition, non-case comparison group, study quality, confounder adjustment). Only antibiotic classes with data from at least 10 studies were included in the sub-group analysis. The sub-group pooled associations and their corresponding I^2 statistics and tau-squared statistics (for between study variance) were examined. The overall association between the study characteristic was investigated using random effects metaregression; variables associated with between study variation at $p \leq 0.10$ in a bivariate analysis were included in multivariable models.

Funnel plot analysis was used to assess bias due to missing results (publication bias).²¹

Results

The PRISMA diagram is presented in Figure 1. Of 804 titles and abstracts of non-duplicate articles screened, 197 full text articles were assessed for eligibility and 23 were included in the review along with 16 studies from the previous review covering studies until the end of 2012 (total 39). Of the 23 studies identified from the latest searches, only 11 studies reported a clear definition of hospital acquisition with a further 12 deemed probable HCFA-CDI based on information available in the

article. Two papers previously excluded from the earlier review (consisting of 14 studies) were identified as probable HCFA-CDI and subsequently added to this update.

Four studies of patients undergoing solid organ transplants²²⁻²⁵ and five stem cell transplant studies²⁶⁻³⁰ were excluded because of the long follow times after discharge precluding establishment of HA. For example, in the study by Cusini et al.²² kidney transplant patients were followed for 2 years of which only 56% of CDI cases were deemed nosocomial.

Description of studies

The characteristics of the included studies identified are summarised in Table 1. Full details of each study identified are provided in the supplementary file (Table S1). Most studies were either cohort or case-control studies, where cohort studies were the predominant design in articles published since 2013, compared to case-control studies in earlier articles. Compared to the earlier review, a more diverse range of patient groups was investigated in the recent studies and from a wider range of geographic regions. Of the 18 cohort studies, 16 were clinical cohort studies, examining specific inpatient sub-groups. Most studies at both time points used patients not diagnosed with CDI as the non-case group, with 23% using symptomatic non-cases. Most studies (87%) used non-exposure to the antibiotic of interest as the unexposed comparator.

Quality appraisal

Most studies were graded as medium or high quality (Table 1). Full details of the NOS quality appraisal score for each study is summarised in the supplementary file (Table S2). Selection and confounding were important sources of error, with only 17 (43%) studies attaining the maximum score for selection and 15 (38%) studies reaching the maximum score for comparability; 86% of case-control designs scored 3/3 for exposure measurement, and 50% of cohort designs scored 3/3 for outcome measurement.

Study results and pooled effects

Studies that used an exposure comparison group consisting of those not exposed to the antibiotic measured were included in meta-analyses (n=34).

For non-beta-lactam antibiotic classes (Figures 2 and 3), the strongest evidence for an association was seen for quinolones (fluoroquinolones) and lincosamides (clindamycin). Overall, quinolones were associated with a 34% increased odds of HCFA-CDI (OR=1.34, 95% CI=1.13-1.60), although individual ORs ranged from 0.15 to 15.30. Excluding the study with an extremely small outlier association (0.15) made little change to the pooled result (OR=1.37, 95%CI=1.15-1.63; $I^2=85.4\%$). Lincosamides were associated with a 56% increased odds of HCFA-CDI (OR=1.56, 95% CI=1.13-2.14), with individual study ORs ranging from 0.39 to 9.10. Weak positive pooled associations were observed for aminoglycosides, macrolides, and sulphonamides-trimethoprim, and a wide range in individual study effect sizes was found. There was strong heterogeneity observed for each of these classes, with ORs distributed in both positive and negative directions. Associations were found also for antibiotics used to treat CDI, particularly vancomycin (class glycopeptides) with a pooled OR of 1.91 (95%CI 1.32-2.78).

Figure 4 displays the results for beta-lactam classes. The strongest association was seen for carbapenems (OR=2.55, 95%CI=1.83-3.55), with penicillins and cephalosporins associated with 33% and 79% increased odds of HA-CDI, respectively. There was substantial heterogeneity for all three main classes. For carbapenems, all ORs except one were in the positive direction ranging from 0.79 to 14.13. For penicillins and cephalosporins there were a number of ORs in opposite directions.

Beta-lactamase inhibitor combination penicillin antibiotics were the most frequently reported penicillin sub-class (Figure 5). ORs ranged from 0.47 to 17.40 (three studies had OR<1) with a pooled OR of 1.43 (95%CI 1.16-1.77). There was little evidence of an association for aminopenicillins, and few studies reported data for broad-spectrum or penicillinase-resistant penicillins.

For cephalosporins, 3rd and 4th generation classes were associated with a doubling of the odds of HA-CDI, 2nd generation cephalosporins with a 58% increased odds of HA-CDI, and no evidence for an association with 1st generation cephalosporins (Figure 6). The individual study findings for 4th generation cephalosporins were the most homogenous, with all effect sizes in a positive direction and ranging from 1.1 to 3.24.

Metaregression and sub-group analyses

Ten antibiotic classes with a minimum of 10 studies and where more than 50% of the variation was due to heterogeneity were included in the sub-group analysis and metaregression. The results of subgroup analyses are presented as supplementary figures (Figures S1-S3). Although several sources of heterogeneity were identified for eight antibiotic classes, there were no sources common to all classes (Table 2). The most common sources were geographic region, exposure measurement period, and measurement of exposure after onset of symptoms.

Studies conducted in Latin America, East Asia and Pacific regions reported stronger associations for combination penicillins, aminoglycosides and trimethoprim-sulfonamides, approximately 3-4 times higher than those reported by North American studies. Measurement of the antibiotic exposure after onset of symptoms was also a source of heterogeneity for aminoglycosides, with associations twice that of studies that collected exposure information preceding onset of symptoms. A longer window of antibiotic exposure measurement was associated with all three cephalosporin sub-classes in unadjusted analyses, and associations were attenuated in multivariable models. Other sources of heterogeneity for cephalosporins included definition of HCF acquisition (2nd and 3rd generation), study population (3rd generation) and study design (3rd generation). Studies using patient sub-groups tended to have weaker associations for a number of antibiotic classes, and this was a strong source of heterogeneity for associations with macrolides and 3rd generation cephalosporins, with effect sizes half of that seen in studies of general inpatients.

Other findings

Five studies were not included in the meta-analysis due to differences in antibiotic exposure measurement; two Canadian studies used no antibiotic exposure as the reference category,^{31,32} one study examined duration and dosage of antibiotic exposure³³ and two UK studies used historical controls to examine the impact of changes to antibiotic formulary changes.^{34,35} The main results are summarised below.

A case-cohort study of adult inpatients of a large tertiary hospital in Canada measured the risk of HA-CDI associated with exposure to various antibiotic classes compared to patients with no antibiotic exposure in the five days prior to developing symptoms.³¹ After adjusting for age, gender, hospital exposure, and infection pressure, the incidence of CDI was 2-3 times higher for penicillins, cephalosporins, fluoroquinolones, and carbapenems. The second Canadian study compared the risk of CDI for various antibiotics according to whether CDI developed during or following cessation of exposure compared to no exposure, taking into account competing events of death or discharge.³² They found the risk of CDI was greatest in the period following exposure to penicillins, quinolones, macrolides, aminoglycosides or clindamycin.

The cohort study of ICU patients with hospital-acquired pneumonia by Li *et al.*³³ reported the mean duration of treatment and total dose per patient to be higher in patients who developed CDI for broad-spectrum cephalosporins, carbapenem, and oxacephems, although not all of the differences were statistically significant.

Two UK clinical cohort studies used historical controls to examine the impact of changes to antibiotic formulary changes. In patients with severe hospital-acquired pneumonia, none of the patients treated with amoxicillin plus temocillin (n=98) developed CDI compared to 7.4% (7/94) of patients who had previously been treated with piperacillin-tazobactam (both beta-lactamase inhibitor combinations).³⁴ In a study comparing gentamicin (aminoglycoside) with cefuroxime (2nd generation cephalosporin) for total hip and knee replacement surgery prophylaxis, there were no CDI cases in the gentamicin group (n=2101) compared to 11 cases (0.2%) in the cefuroxime group (n=6094).³⁵

Non-English language studies

Thirteen non-English language articles were identified in the current review of which only one study was eligible for inclusion in the review.³⁶ The case-control study of immunosuppressed patients reported exposure to fluoroquinolones was higher in CDI cases (36%) than controls (28%) and exposures to 2nd or 3rd generation cephalosporins was lower in cases (6%) than controls (14%). Details of the non-English language studies are summarised in Table S3.

Funnel plot symmetry

Supplementary Figure S4 displays the funnel plots for the studies included in the meta-analyses of each main antibiotic class. Although there was not strong evidence for bias due to non-reporting of small studies, several of the plots reflect asymmetry associated with the heterogeneity previously addressed.

Discussion

This systematic review updates the findings from two previous reviews through to 2020. Twenty-one studies published since 2013 were included in this review, in addition to 16 studies identified in earlier reviews.^{10,11} The main findings indicate that carbapenems and 3rd and 4th generation cephalosporin antibiotics remain most strongly associated with HCFA-CDI, with cases more than twice as likely to have recent exposure to these antibiotics prior to developing CDI. Modest associations (OR>1.5) were observed for quinolones (predominantly fluoroquinolones), lincosamides (namely clindamycin), 2nd generation cephalosporins, and beta-lactamase inhibitor combination penicillin antibiotics. Individual study effect sizes were variable and heterogeneity was a common problem observed for most antibiotic classes. However, the risk of CDI for a given antibiotic will depend on the local prevalence of strains that are resistant to the particular antibiotic and a certain degree of heterogeneity is therefore to be expected.⁸

Since 2013, there have been more studies conducted in a wider range of countries, including three from Latin America (covering Argentina, Mexico, Brazil)^{37,38} and four from East Asia and Pacific countries (China, Korea, Malaysia, Taiwan).^{33,39-41} The studies from Latin America and East Asia-Pacific regions reported stronger associations for a number of antibiotic classes with HCFA-CDI. With only a small number of studies from these regions conclusions regarding such differences are limited and further studies are needed.

In addition, a more diverse range of patient populations have been studied since 2013, with an increase in focused studies on clinical patient groups, such as surgical^{35,42,43} and ICU patients,⁴⁴ or patients with particular conditions such as HA-pneumonia,^{33,34,45} compared to earlier studies that

predominantly studied general inpatients. Studies using patient sub-groups tended to have weaker associations. A potential explanation is that studies of patient sub-groups had shorter periods of antibiotic exposure measurement. For example, in studies assessing 3rd generation cephalosporins, three out of seven studies of general inpatients measured exposure up to three months prior to CDI, whereas no study that was restricted to patient sub-groups used a three-month exposure window. Studies that used longer windows of exposure measurement had stronger effect sizes which could reflect a protracted time at risk for CDI following antibiotic treatment. Previous studies have shown that the risk of CDI declines between 1-2 months following cessation of antibiotic treatment.^{31, 46} Alternatively, it could mean that these studies simply picked up more exposed individuals, resulting in differential misclassification if this was not consistent for cases and non-cases.

Another exposure measurement source of heterogeneity was the inadequate description or failure to limit recording of antibiotic exposure to a period preceding onset or diagnosis of CDI, producing biased effect estimates. This could explain the associations found for antibiotics used to treat CDI such as vancomycin and metronidazole (glycopeptide and nitromidazole classes, respectively), although this could not be established in this review, and both are able to incite CDI.⁴⁷ Future studies should clearly report the parameters of exposure measurement, including all sources of information on exposure, as it was often unclear particularly in studies with a longer exposure window whether in-hospital prescription only was recorded, or whether prescription in the community setting was included. Information on dose-response relationships is generally lacking and studies investigating the risk of HCF-CDI associated with the timing and duration of antibiotic exposure are needed.

Other methodological differences in studies, such as the use of a clear definition of hospital-acquisition, the choice of non-case comparison group, and group comparability on confounding factors, were not consistent sources of heterogeneity, but had varying influences on study results. A variety of diagnostic laboratory testing methods that have varying sensitivity and specificity were used by studies included in the review. With increasing computing power, cohort studies utilising routinely collected patient data have increased in recent years - investigators should clearly report surveillance definitions, criteria and laboratory methods for diagnosis of CDI in their institutions, and how these align with relevant current guidelines.^{8, 48} Studies are subject to diagnostic suspicion bias if patients exposed to antibiotics are more likely to be tested for *C. difficile*.

This review provides the most up to date synthesis of evidence in relation to the risk of HA-CDI associated with exposure to specific antibiotic classes. However, the review is limited by the availability of a single reviewer to select, extract and critically appraise the studies. Since the previous review that covered studies published up to the end of 2012, there has been a marked increase in the overall number of studies eligible for inclusion. As found previously, studies were variable in methodological quality and quality of reporting results. Studies from the Latin America and East Asia-Pacific regions have increased, although studies were predominantly conducted in North America or Europe, and more studies outside of these settings are needed.

Table S1. Characteristics of included studies of antibiotics and HA-CDI, 1st January 2013 to 31st December 2020

Author & year	Methods	Primary aim of study	Participants	Antibiotic exposure	Outcome	
					HA-CDI case definition	Non-cases
Brown 2014 ¹	Case cohort study	CDI risk associated with duration of antibiotic therapy.	Adults (>18 years) admitted to a tertiary hospital. 1st Jun 2010 to 31st May 2012. Canada.	Pharmacy dispensing records during admission within 5 days of (i) symptom onset for CDI cases, and (ii) discharge, study termination or death for non-cases.	During hospital stay either: (i) visualisation of pseudomembranes, or (ii) diarrhoea (2 or more loose/watery stools in a 24-hour period with no other recognised etiology) plus positive stool PCR toxin assay for <i>C.difficile</i> . HA definition: Onset >2 days after admission	10% random sample of non-CDI cohort.
Cannon 2017 ²	Clinical cohort study	Risk of CDI during hospitalisation for hematology-oncology patients colonised with <i>C.difficile</i> .	Admissions (LOS>1) to hematological malignancy/bone marrow transplant unit in 566-bed hospital. 12th May 2015 to 24th Sep 2015. USA.	Electronic medical record within previous 30 days	During hospital stay: Diarrhoea (following IRDS/SHEA 2010 guidelines) and positive test for <i>C.difficile</i> (culture plus PCR). HA definition: Diagnosis > 24h after admission	Patients that did not develop symptomatic CDI
Debast 2014 ³	Case control outbreak study	Identify risk factors for CDI during an outbreak.	Adult inpatients of a 341-bed hospital. Apr to Sep 2005. Netherlands.	Pharmacy database records for antibiotics prescribed within and outside the hospital for preceding 3 months.	During hospital stay: Diarrhoea (2 or more loose bowel movements per day) and positive stool <i>C.difficile</i> toxin EIA (Immunocard Toxin A/B, Meridien) followed by culture and PCR toxin typing. HA definition: not stated; 44/45 probable HA	Patients residing at the same time and the same ward. 1. Non-CDI diarrhoea 2. Patients without diarrhoea

Forster 2017 ⁴	Cohort study	To determine the potential effects of interventions on hospital-acquired CDI risk	Adult inpatients (>18 years) of a 1000-bed tertiary care hospital. 1st Mar 2004 to 1st Mar 2014. Canada.	Pharmacy database records of exposure to antibiotic class during admission.	During hospital index admission: Unformed stool sample with positive stool EIA for toxin A or B (Bio Nuclear Diagnostics). HA definition: samples taken >48 hours after admission and up to 1 month after discharge.	Patients that did not develop symptomatic CDI
Gaertner 2015 ⁵	Nested clinical case control study	To review and compare outcomes of patients with and without CDI infection after elective colorectal operations.	Patients undergoing elective colon or rectal surgery. Jan 2007 to Dec 2012. USA.	Nursing, anaesthesia and operative records of preoperative prophylaxis antibiotic	Up to 30 days post-operative: ICD code 008.45 from hospital database with chart confirmation of positive <i>C.difficile</i> toxin assay (PCR or EIA) and postoperative diarrhoea (≥ 3 loose or liquid stools per day) or high stoma output (>2000ml per day). HA definition: unclear. Minimum time from surgery to CDI 2 days	Matched on age, diagnosis and procedure performed: 1. Diarrhoea with negative toxin assay 2. Patients without an assay
Gutierrez-Pizarraya 2018 ⁶	Clinical cohort study	To describe the incidence, clinical characteristics, and risk factors for CDI in critically ill patients.	Patients who developed diarrhoea during ICU stay (26 ICUs). 3rd Feb to 3rd Apr 2014. Spain.	Source not stated; antibiotics within 30 days prior to onset of diarrhoea.	During ICU stay: Development of diarrhoea (≥ 3 unformed stools within 24 hours) with positive test for <i>C.difficile</i> (method not provided). HA definition: not defined. 94% of sample developed diarrhoea >48 hours after admission.	Patients with diarrhoea and negative test for <i>C.difficile</i>
Habayeb 2015 ⁷	Clinical cohort with historical controls	To assess the effect of a formulary change for treatment of severe hospital-acquired pneumonia (HAP)	Inpatients with severe HAP in an acute care hospital. Jan 2011 to Jul 2012. UK.	Pharmacy records of patients treated with amoxicillin plus temocillin (Nov 2011 - Jul 2012) compared to patients treated with piperacillin/tazobactam (Jan 2011 - Nov 2011)	During inpatient treatment for severe HAP: Development of diarrhoea (at least 2 episodes of type 6 or 7 stools on Bristol stool chart in 24 hours) and positive test for <i>C.difficile</i> (stool toxin A and B detection up to 2012 followed by two-step GDH and toxin immunosassay). HA definition: assumed on basis of HAP definition (> 48h after admission)	Patients that did not develop CDI

Hassan 2013 ⁸	Clinical cohort	Determine the rate and characteristics of HA-CDI in subjects with type 2 diabetes admitted into acute medical wards.	Adult patients (>18 years) with type 2 diabetes consecutively admitted to acute medical wards in 700-bed tertiary hospital. Aug 2009 to May 2010. Malaysia.	Source not stated; antibiotic prescription covering at least 48 hours in the last 8 weeks prior to <i>C.difficile</i> infection.	During admission: Diarrhoea (>3 loose stools within a 24 hour period for >2 days) and two positive stool Toxin A/B tests (different test kits) HA definition: >48 hours after admission or <48 hours if patient hospitalised within 4 weeks prior to admission.	Patients not diagnosed with HA-CDI
Kirkwood 2018 ⁹	Clinical cohort	Characterise the incidence and risks of CDI in cardiac surgery patients.	Cardiac surgery patients (≥18 years), multicentre (10 sites). Feb and Sep 2010. USA & Canada.	Source not stated; pre-operative antibiotic prophylaxis.	During 65 days postoperative follow-up: CDI diagnosis as per standard clinical practice at each site. HA definition: not defined. Minimum time to CDI onset = 8 days	Patients without CDI
Li 2017 ¹⁰	Clinical cohort	Examine the risk and disease burden of CDI amongst hospitalised HAP patients.	Patients admitted to ICU in a 3500-bed tertiary hospital with HAP who developed hospital onset diarrhoea. Jan to Dec 2014. China.	Medical records of antibiotics used for HAP therapy.	During admission: Hospital onset diarrhoea (≥3 episodes within 24 hours) and detection of toxin-producing <i>C.difficile</i> by culture and PCR. HA definition: ≥48 hours after hospital admission	Patients with hospital onset diarrhoea and negative for <i>C.difficile</i>
Lin 2015 ¹¹	Clinical cohort study	Examine risk factors for CDI amongst hospitalised patients colonised with toxigenic <i>C.difficile</i> .	Inpatients (≥18 years) with toxigenic <i>C.difficile</i> colonisation admitted to medical ward of a district general hospital. Jan 2011 to Jun 2012. Taiwan.	Medical records of antibiotics prescribed within one month before CDAD or end of follow-up.	During admission including repeat admissions (follow up until discharge, death or end of study period): Diarrhoea (3 loose stools within at least a 2-day period) and detection of toxin-producing <i>C.difficile</i> by culture and PCR. HA-definition: not specified. Screened for colonisation within 48 hours, follow-up for development of CDI	Asymptomatic colonised patients

Lopardo 2015 ¹²	Clinical cohort study	Describe occurrence of <i>C.difficile</i> .	Inpatients at four tertiary care hospitals aged ≥40 years who received antibiotic treatment. 21st Sep 2010 to 19th Sep 2011. Mexico and Argentina.	Source not stated; antibiotics prescribed during hospitalisation prior to onset of CDI.	Follow up for 30 days after start of antibiotic therapy Clinical suspicion of CDI (i.e. antibiotic-associated diarrhoea [3 or more stools in a 24 hour period]) and positive ELISA test for <i>C.difficile</i> toxins A or B and toxigenic culture (if positive on ELISA). HA definition: not specified. Minimum time from admission to symptoms 3 days	Patients that did not develop CDI.
Maestri 2020 ¹³	Clinical cohort study	Identify prevalence, clinical characteristics, treatment, and recurrence of CDI in patients with antimicrobial-associated diarrhoea.	Adult inpatients aged ≥18 years from eight hospitals who developed antimicrobial-associated diarrhoea. 2017-2019. Brazil.	Standardised questionnaire of antimicrobials received in 90 days preceding diarrhoea onset.	During admission; diarrhoea (≥3 liquid stools per day) and a stool test positive for toxin producing <i>C.difficile</i> by EIA or qPCR. HA definition: not specified. Hospitalised >48 hours after admission.	<i>C.difficile</i> negative patients with antimicrobial-associated diarrhoea
Matthaiou 2019 ¹⁴	Clinical cohort study	Investigate incidence of CDI in Greek ICUs and identify potential risk factors for CDI	Patients hospitalised in 3 ICU units for more than >72 hours who developed diarrhoea. 1st Jan 2014 to 31st Dec 2014. Greece.	Source not stated; antibiotics prior to and during ICU admission.	During ICU admission: Diarrhoea (≥3 watery stools per day) and positive test for <i>C.difficile</i> (GDH and toxin A/B; toxigenic culture) and any of the following clinical signs: leukocytosis >15000 per mm ³ , dehydration/hypotension, shock, ileus, and megacolon. HA definition - not specified. HA-CDI stated in abstract.	<i>C.difficile</i> negative patients with diarrhoea

Pakyz 2014 ¹⁵	Case control study	Determine patient- and hospital-level medication risk factors associated with CDI	Multicentre study of patients ≥18 years of age admitted to 64 medical centres. 2009. USA.	Database extraction of antibiotic exposure prior to index date (date of initiation of CDI therapy for cases; date of discharge for controls).	During admission: ICD-9-CM code 008.45 and received drug treatment for CDI (metronidazole or oral vancomycin) for at least 3 days. HA definition: commencement of CDI treatment ≥3 days after admission	Patients without ICD code for CDI frequency matched on pre-CDI length of stay and clinical service lines reflecting diagnosis related groups.
Predrag 2016 ¹⁶	Case control study	Determine risk factors important for the development of HA-CDI	Patients admitted to a regional hospital with LOS ≥ 48 hours who developed diarrhoea. Jan 2013 to Jun 2014. Serbia.	Patient records for antibiotics received up to 60 days prior and during diarrhoea.	Diarrhoea (≥3 unformed or liquid stools over 24 hours for at least 2 days) or toxic megacolon and positive laboratory assay for <i>C.difficile</i> toxin A and/or toxin B in stools, or toxin producing <i>C.difficile</i> detected in stool via culture or other means. HA definition: hospitalised for at least 48 hours prior to developing symptoms.	Patients with diarrhoea and negative test for <i>C.difficile</i> . Matched on hospital, age, sex, month of admission.
Silva 2017 ¹⁷	Case control study	Identification of asymptomatic carriers of <i>C. difficile</i>	Inpatients of 670-bed hospital. Feb 2015. Brazil.	Medical records of antibiotics prior to <i>C.difficile</i> testing (current admission and 1 week prior to admission).	Diarrhoea and positive PCR for <i>C.difficile</i> toxin B and binary toxin (nucleic acid amplification) HA definition: >72 hours after admission or within 72 hours of discharge from facility.	Inpatients receiving antibiotics but with no diarrhoea matched on location.
Song 2020 ¹⁸	Clinical cohort study	Investigate temporal changes in incidence and risk factors for <i>C. difficile</i>	Pediatric and adult inpatients from three metropolitan New York hospitals with antibiotic exposure, Sep 2009 to Dec 2016. USA.	Medication administration record up to 1 day prior to <i>C. difficile</i> diagnosis (or hospital discharge for <i>C. difficile</i> negative group).	During admission: Unformed stool with positive toxin detection by real-time PCR. HA definition: CDI diagnosed ≥ 3 days after admission.	Received antibiotics but no diagnosis of <i>C. difficile</i>

Sprowson 2013 ¹⁹	Clinical cohort study with historical controls	Evaluate impact of change of antibiotic prophylaxis for joint replacement.	Patients undergoing primary total hip and knee replacement, three district hospitals. Jan 2002 to Feb 2009. UK.	Hospital episode patient records for gentamicin prophylaxis (1st Oct 2007 - 26th Feb 2009) compared to cefuroxime prophylaxis (1st May 2002 - 30th Sep 2007)	Within 30 days of surgery: ICD-10-CM code A047 for <i>C.difficile</i> . HA definition: onset day 3 or later, or if within 3 days patient had been discharged from an acute care facility less than 28 days before current admission.	<i>C.difficile</i> negative patients.
Stefan 2013 ²⁰	Clinical cohort study	Investigate association between antibiotic treatment and outcomes in patients hospitalised with AE-COPD treated with systemic steroids.	Multicentre (410 sites) study of inpatients aged ≥40 years with severe acute exacerbations of COPD (AE-COPD) who were treated with systemic corticosteroids. 1st Jan 2006 to 1st Dec 2007. USA.	Inpatient administrative database for treatment regimen.	Readmission within 30 days with diagnosis of <i>C.difficile</i> (details not provided). HA-definition: not provided Source: administrative database	No diagnosis of <i>C.difficile</i>
van Werkhoven 2015 ²¹	Clinical case-cohort study	To develop and validate a prediction model for CDI in hospitalised patients treated with antibiotics.	Inpatients (>16 years) treated with systemic antibiotics, 1042-bed tertiary care hospital. Jan 2005 to Dec 2011. Netherlands.	Patient records for systemic antibiotics during hospitalisation.	CDI during hospitalisation and up to 28 days following discharge: Diarrhoea (not defined) and positive <i>C.difficile</i> stool toxin A or B test (ImmunoCard) HA definition: none stated. Minimum LOS to diagnosis 3 days.	Random selection of hospitalised patients receiving systemic antibiotics not diagnosed with CDI.
Watson 2018 ²²	Retrospective cohort study	To analyse the association of HO-CDI with the use of acid suppressing drugs and frequently used antibiotics	Multicentre study (150 sites) of inpatients >18 years. 1st Oct 2015 to 30th Sep 2016. USA.	Patient database for antibiotics during admission period.	During hospitalisation: Hospital onset CDI positive: Unformed stool and positive stool test for toxigenic <i>C.difficile</i> or toxin-coding genes. HA definition: stool collected >3 days after admission	Patients without hospital onset CDI

<p>Yang 2014²³</p>	<p>Clinical cohort study</p>	<p>To identify risk factors for PMC that can be applied to the treatment of HAD.</p>	<p>Patients aged 20 years or over with hospital-acquired diarrhoea (HAD) recruited from medical or surgical departments in a university hospital. Jun 2007 to Sep 2011. Korea.</p>	<p>Chart review for antibiotics during admission before diarrhoea.</p>	<p>During admission period: Diarrhoea and positive PCR and stool culture for <i>C.difficile</i> or pseudomembranous colitis diagnosed by endoscopy.</p> <p>HA definition: >48 hours after admission</p>	<p>HAD patients without <i>C.difficile</i> infection</p>

Table S3. Features of eligible studies published in non-English languages

Study citation	Country	Study period	Reason for exclusion	Study population	Study design	Key results
Carvajal 2017 ²⁴	Colombia	2010-2012	Wrong exposure (antibiotic classes not reported)	Inpatients with hospital-acquired diarrhoea	Nested case control study N=123 (30 CDI)	Previous antibiotic exposure: OR=1.22 (95% CI 0.6-3.6) in multivariate analysis.
Herzog 2015 ²⁵	Germany	2004-12	Wrong exposure (antibiotic classes not reported)	Surgical patients	Cross-sectional	Antibiotic risk factors not analysed.
Knyazev 2018 ²⁶	Russia	Unknown	Not HA-CDI (85% of infections were community acquired)	Patients with inflammatory bowel disease	Cross-sectional N=764 (132 CDI)	21.2% of CDI patients had a history of antibiotic use (no comparison data available). Full text unavailable.
Lubbert 2013 ²⁷	Germany	2006-2009	N/A	Immunosuppressed patients	Case-control N=105 (55 CDI)	Prior antibiotic therapy was an independent risk factor for CDI (OR=10.15). Fluoroquinolones: 36% CDI, 28% non-CDI 2/3 rd gen. cephalosporins: 6% CDI, 14% non-CDI
Monge 2013 ²⁸	Spain	2006	Wrong exposure (antibiotic classes not reported)	Inpatients	Retrospective cohort N=114 (38 CDI)	Patients who developed CDI were exposed to a wider range of antibiotics (mean difference 1.5; 95% CI 0.7-2.2)
Polak 2015 ²⁹	Czechia	2011-13	No comparison group	Patients with Campylobacteriosis	Cohort	Incidence of CDI following antibiotic treatment.
Reigadas Ramarez 2015	Spain	N/A	Review article	N/A	N/A	N/A
Rodriguez-Varon 2017 ³⁰	Colombia	2014-15	No comparator group	Patients with antibiotic-associated diarrhoea	Cross-sectional N=43	N/A

Savard 2017 ³¹	Canada	2009-10	Wrong exposure (not antibiotic classes)	Inpatients	Cohort	N/A
Simon 2015 ³²	France					
Sommer 2014 ³³	Denmark	2008	No comparator group	CDI patients	Cross-sectional	N/A
Stepanova 2014 ³⁴	Czechia	Unknown	Unknown	Unknown	Unknown	Unknown
Suljagic 2013 ³⁵	Serbia	2010	Wrong exposure (not antibiotic classes)	Surgical patients	Nested case-control study	Risk of CDI increased with number of antibiotics and duration of use. Number of days of 1 antibiotic: OR=1.2 (95% CI=1.1-1.4) Number of days of 2 antibiotics: OR=1.1 (95% CI=1.0-1.3)

Figure S1. Sub-group analysis – combination penicillins and cephalosporin sub-classes

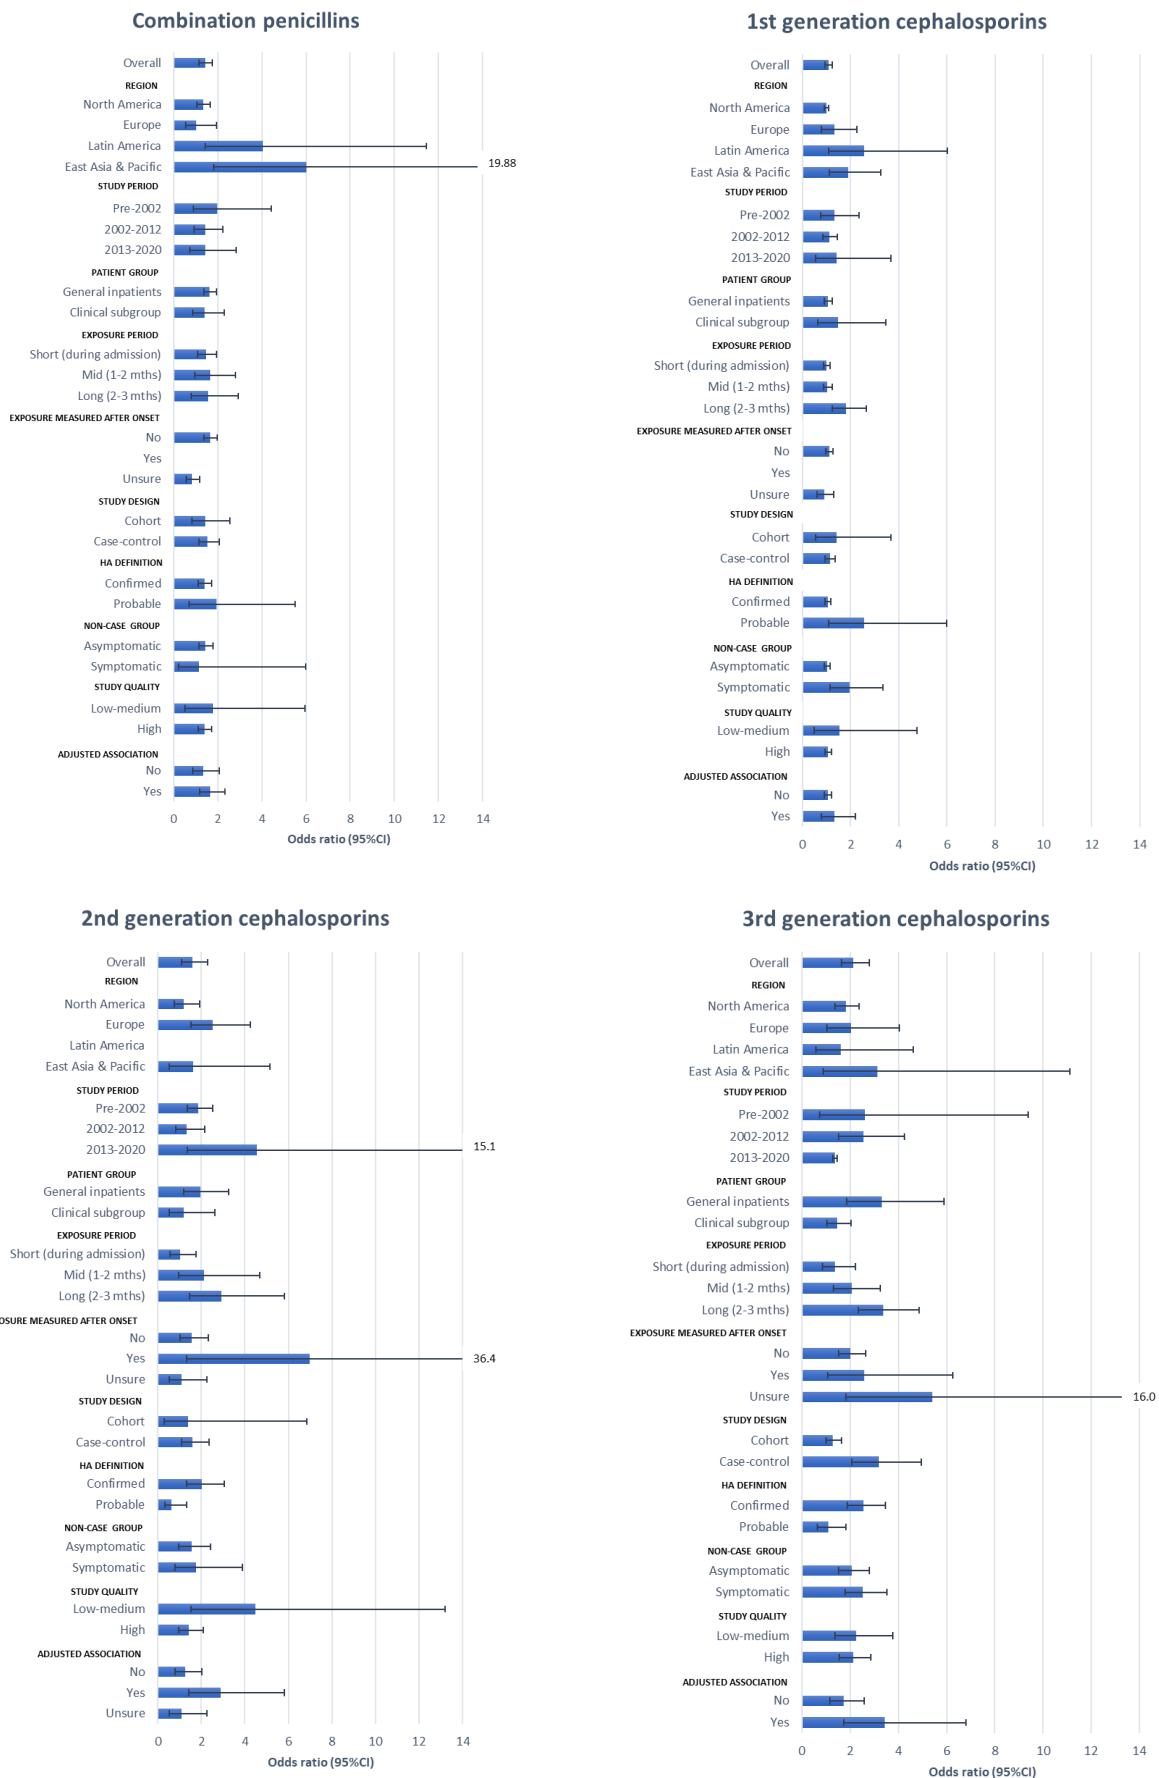

Figure S2. Sub-group analysis – carbapenems, lincosamides, fluoroquinolones, aminoglycosides

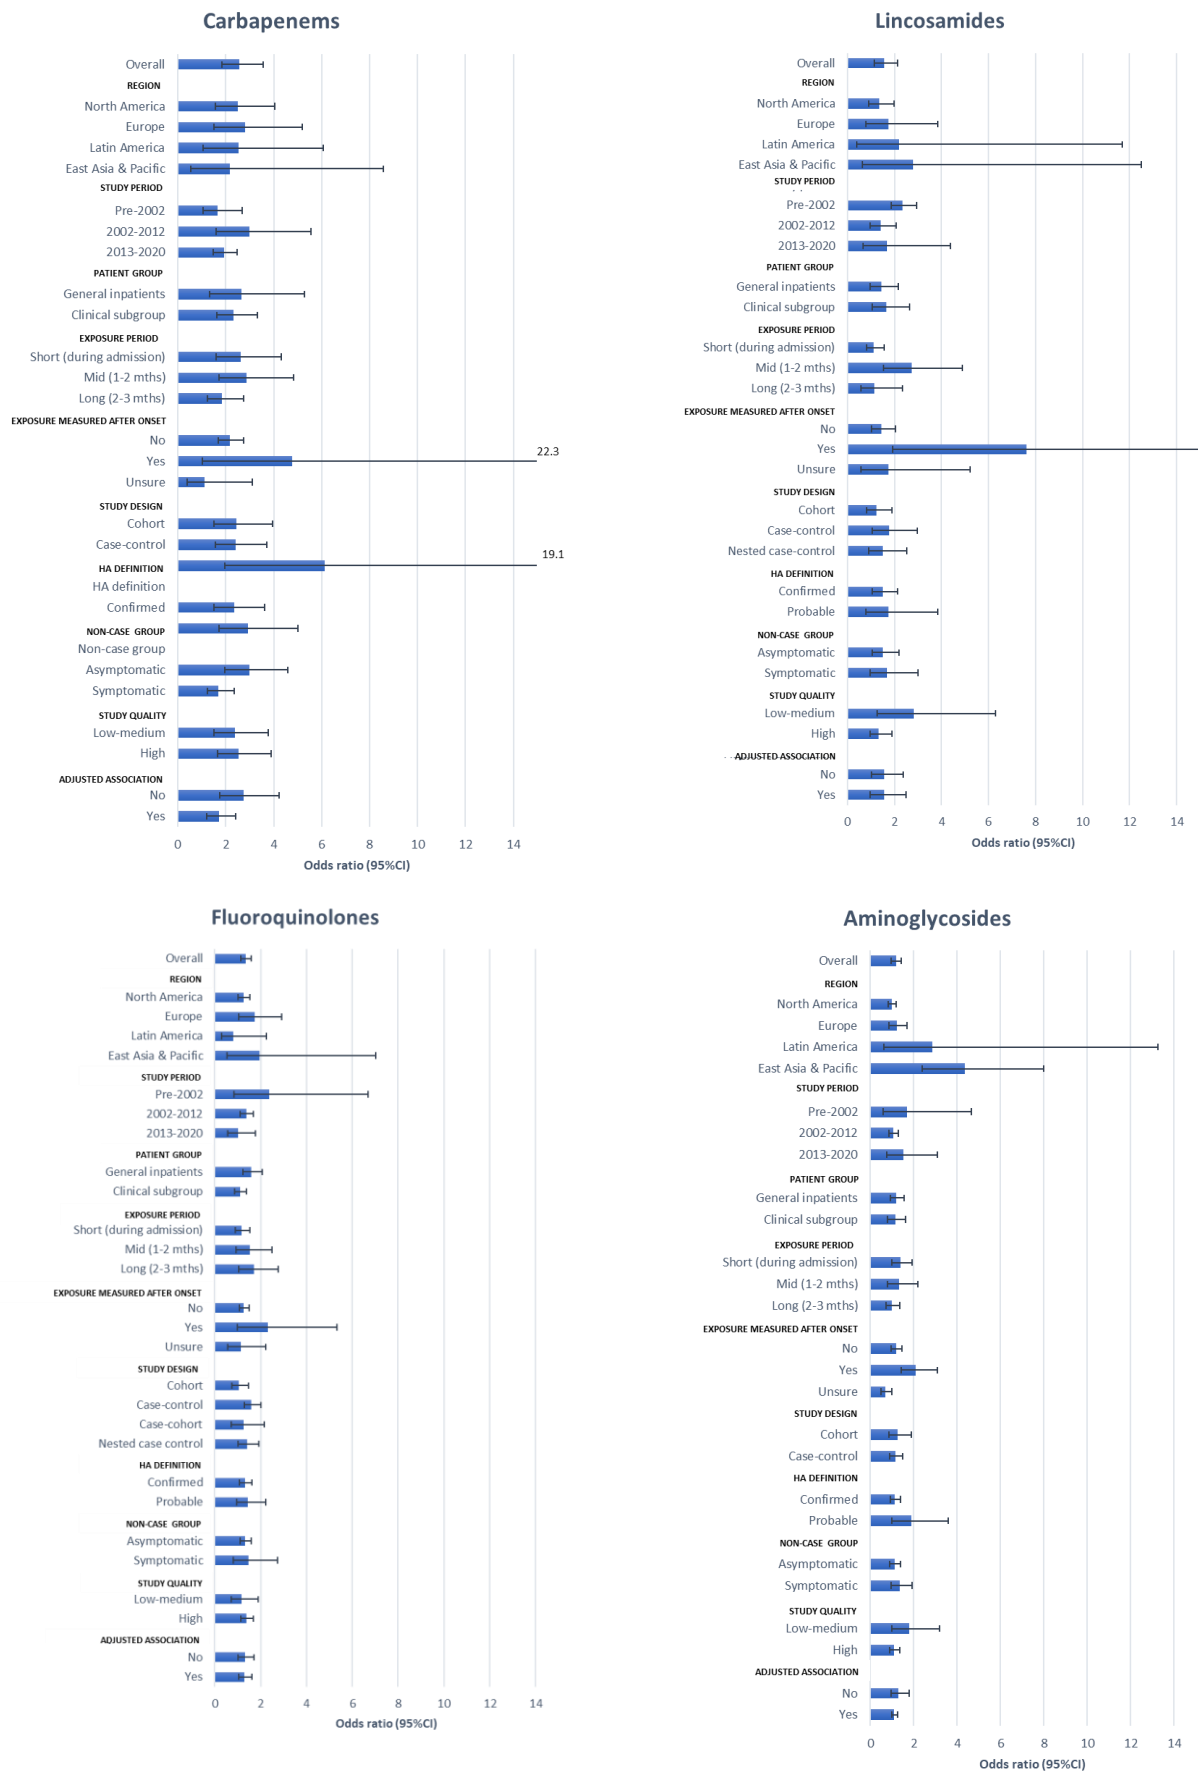

Figure S3. Sub-group analysis – macrolides, trimethoprim-sulfonamides and glycopeptides

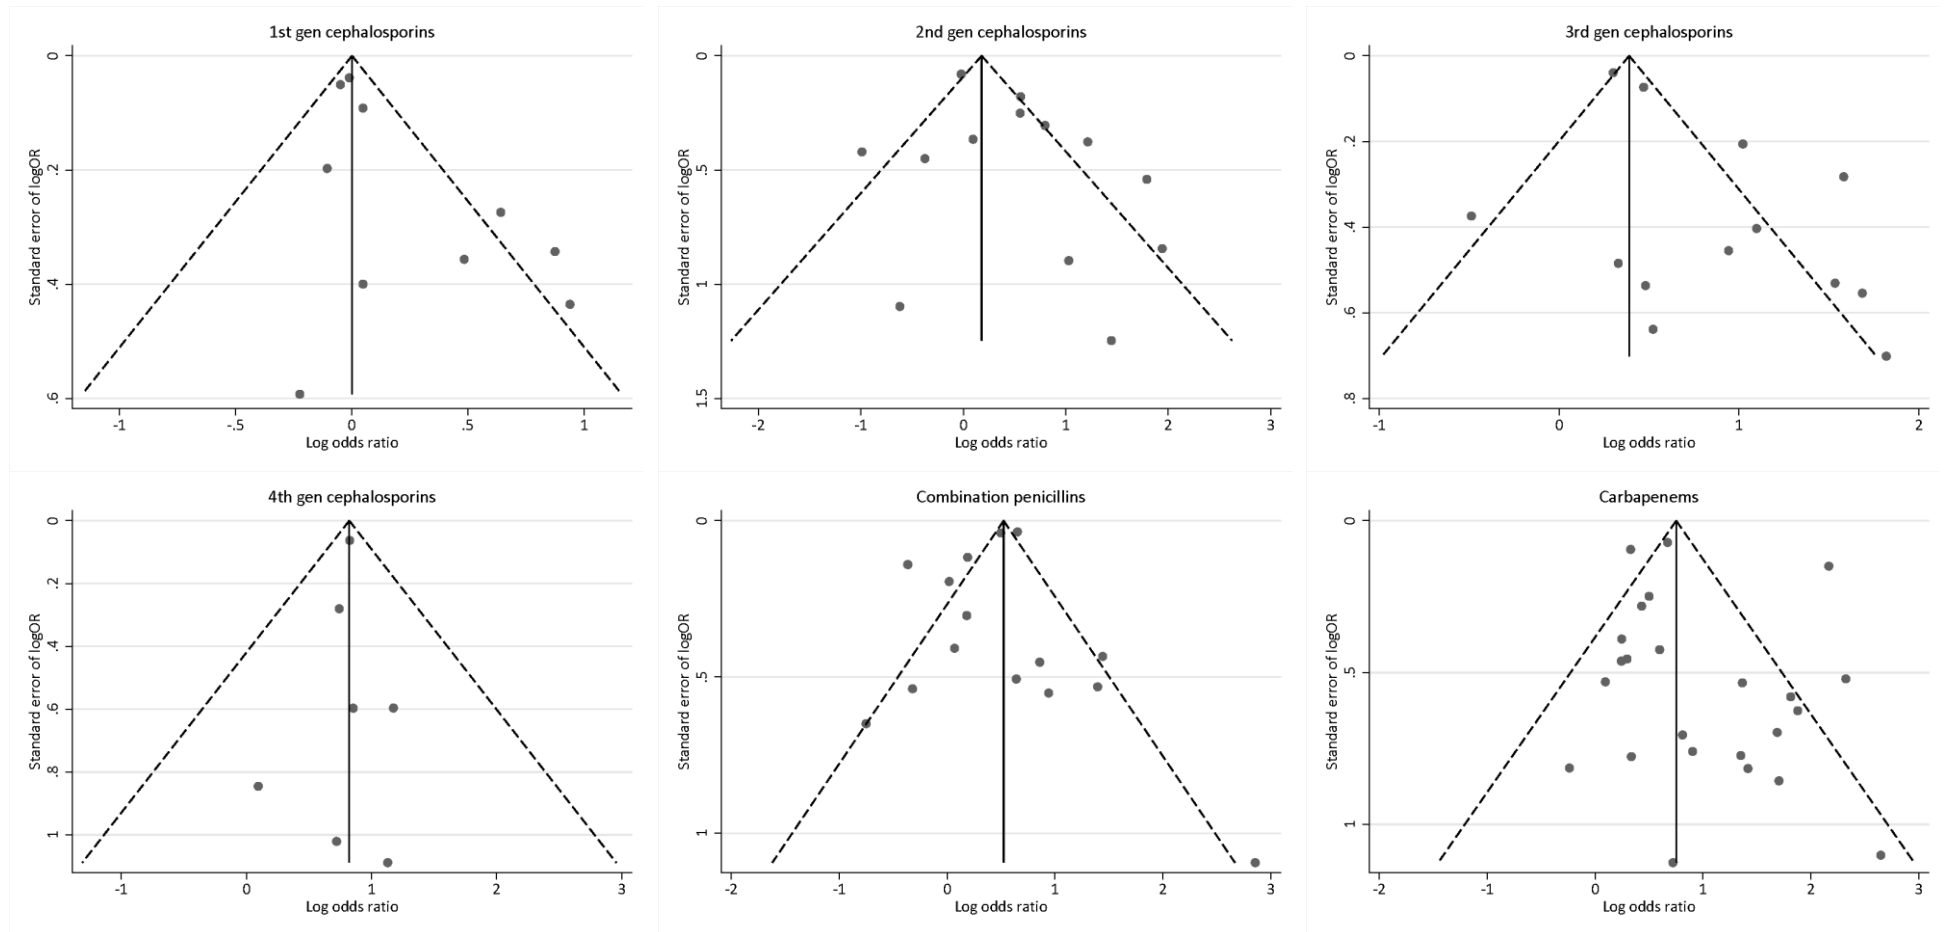

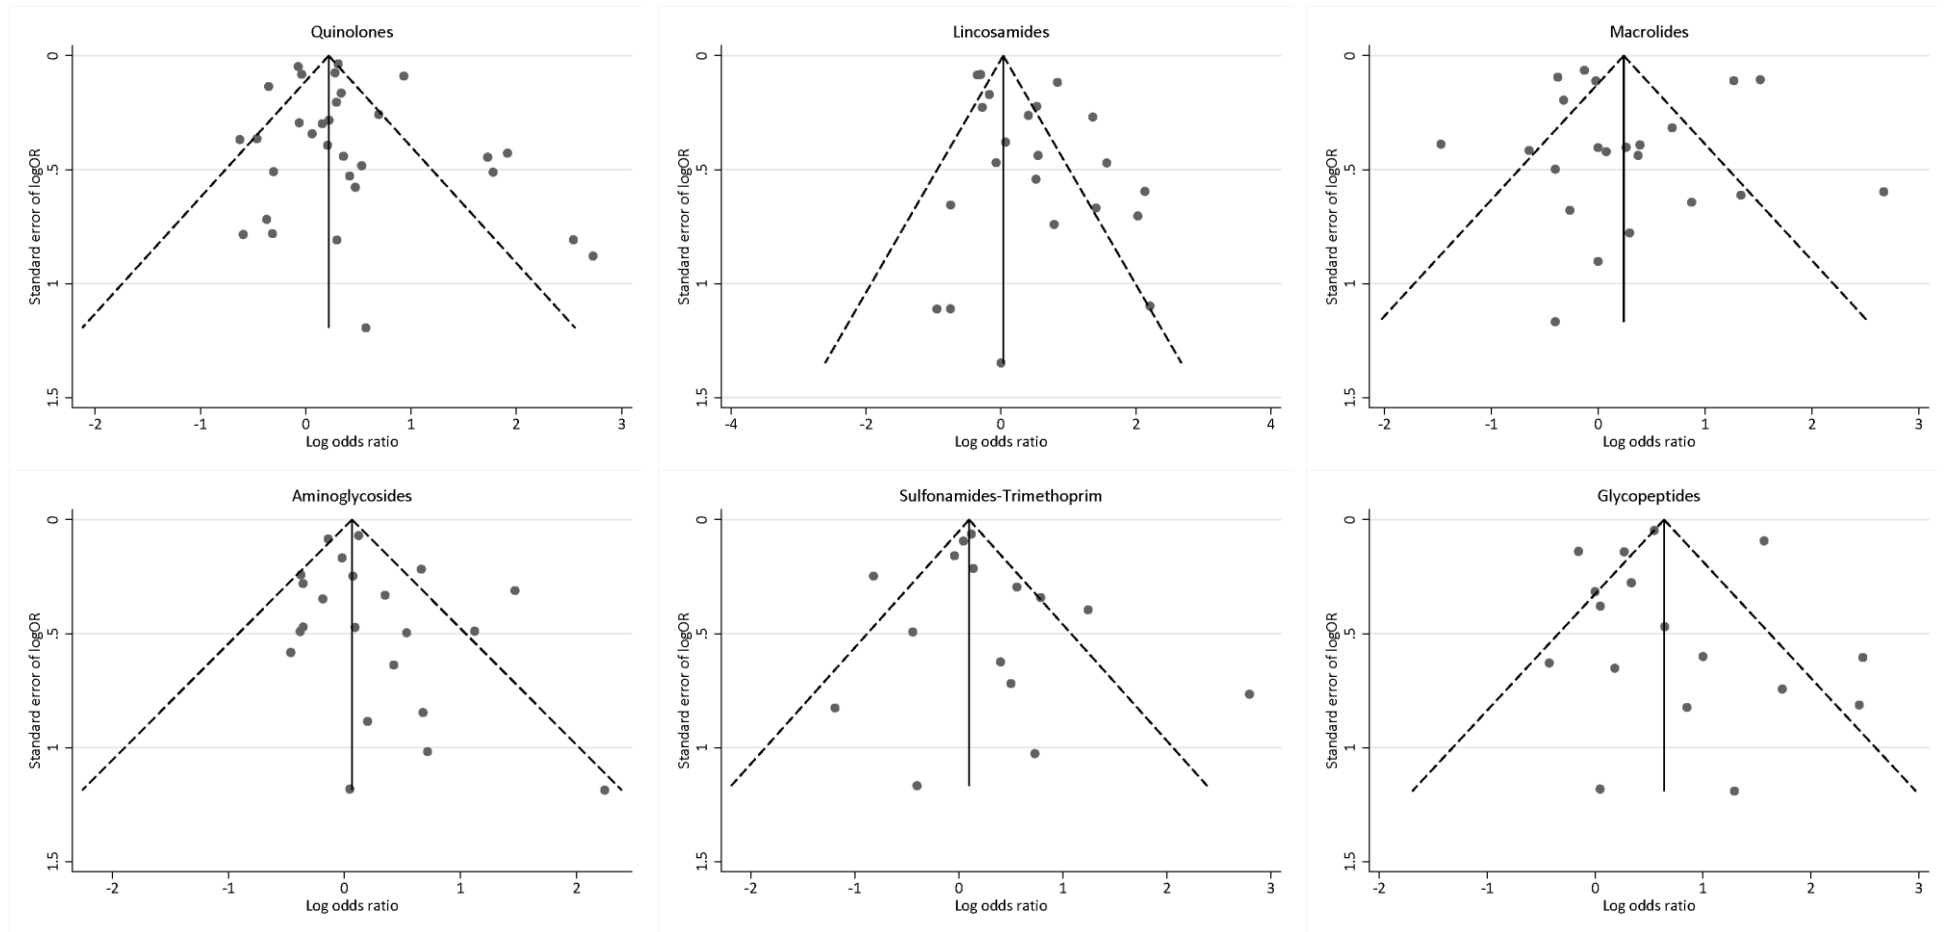

Figure S4 Funnel plots

Note: Effect estimates (x-axis) are plotted against study size (y-axis) as measured by the standard errors of the exposure effect. The Y-axis is plotted on a reverse scale so that the larger studies are at the top (i.e. have smaller standard errors). The effect estimates from smaller studies should scatter more widely at the bottom, with the spread narrowing among larger studies. In the absence of bias and between study heterogeneity, the scatter will be due to sampling variation alone and the plot will resemble a symmetrical inverted funnel.
